*Pontocaine
Hydrochloride*

in

OPHTHALMOLOGY

and in

RHINOLARYNGOLOGY

*Surface Anesthetic
with Prolonged Effect*

Dependable anesthesia
of the mucous membranes

is readily obtained by the topical application of Pontocaine hydrochloride. This widely used agent acts quickly, penetrates deeply, and gives prolonged anesthesia. A variety of operative and nonoperative procedures on the eye, nose and throat may be successfully carried out with small quantities of relatively weak solutions.

HOW SUPPLIED: For surface anesthesia in ophthalmology: 0.5 per cent solution in bottles of ½ oz. and 2 oz.

For surface anesthesia in rhinolaryngology: 2 per cent solution in bottles of 1 oz. and 4 oz.

*Not
a Narcotic*

EDWARD JACKSON'S PLACE IN THE HISTORY OF REFRACTION

FIRST JACKSON MEMORIAL LECTURE*

WILLIAM H. CRISP, M.D.

Denver 2, Colorado

To understand the part played by Edward Jackson in the development of the technique and the teaching of refraction, it seems advisable to review some of the steps which led to our modern knowledge of the subject.

Much of the important work on refraction originated in England and in the United States. One important exception is the famous volume by Donders,⁵ a clinician of Utrecht, Holland; but the complete form of this volume first came before the medical public in an English translation.

It is probable that the first type of refractive error to be subjected to anything like systematic correction was myopia. In 1629, Charles the First of England granted a charter to "The Worshipful Company of Spectacle Makers," one of the organizations which now confer upon British opticians certificates of proficiency in the measurement of optical defects of the eye. It will be remembered that Benjamin Franklin is said to have designed, in 1777, the first pair of bifocal spectacles.

For a long time the terms "presbyopia" and "farsightedness" were used synonymously. The development of a knowledge of astigmatism is relatively recent. Thomas Young, the English physicist, is credited

with the first scientific observation of this ocular defect, correction of which now occupies so large a part of the time of almost every conscientious and well-qualified ophthalmologist.

On November 27, 1800, Thomas Young, M.D. and Fellow of the Royal Society, delivered before that Society his Bakerian lecture²² "On the mechanism of the eye." In that lecture Young described the optical condition of his own eyes, together with certain means of measuring the condition, including a simple optometer. He was strongly myopic as well as astigmatic.

"My eye," he says, "in a state of relaxation, collects to a focus on the retina, those rays which diverge vertically from an object at a distance of ten inches from the cornea, and the rays which diverge horizontally from an object at seven inches distance." Further on he remarks: "The shortest distance of perfect vision in my eye is 26 tenths of an inch for horizontal, and 29 for vertical rays." He adds that he has never experienced any inconvenience from this imperfection! Elsewhere, reference is made to the fact that "Many persons were obliged to hold a concave glass obliquely, in order to see with distinctness, counterbalancing, by the inclination of the glass, the too great refractive power of the eye in the direction of that inclination. . . ."

Young's astigmatism was exceptional

* Presented at the forty-ninth meeting of the American Academy of Ophthalmology and Otolaryngology, October 8-12, 1944.

in two respects. It was what we call inverse, the horizontal meridian having the stronger plus focus. It appears also to have been chiefly lenticular, for one of Young's experiments on his own eye showed that his astigmatism was not abolished when the cornea was immersed in water.

One of Young's scientific activities in relation to the eye consisted of refuting the current belief that the crystalline lens contained muscle fibers. For modern research workers there may be consolation in the following incidental confession of a great scientist: "I beg leave," he says, "to correct here an observation in my former paper, relative to the faint lateral radiations, which I supposed to proceed from the margin of the iris. I find, on further examination, that they are occasioned by reflections from the eyelashes."

Little practical benefit seems to have followed Young's description. But in 1827 Airy,¹ the British Astronomer Royal, reporting before the Cambridge Philosophical Society, described his own case of compound myopic astigmatism and the means taken for its correction. He had observed that the image made in his left eye by a bright point, such as a star or a distant lamp, was not circular but elliptical, the major axis being 35 degrees from the vertical, its upper extremity inclined to the right. He found that, if he drew two lines crossing each other at right angles and placed the paper at a proper distance, one line appeared perfectly distinct while the other could scarcely be seen. On bringing the paper closer to the eye the relation between the two lines was reversed. After "various ineffectual attempts" the construction of the necessary cylindrical lens was accomplished by an Ipswich optician named Fuller, a concave spherical curvature being ground on one side of the lens and a concave cylindrical on the other.

Airy seems to have made one mistake. Toward the end of his short report he says: "I have not been able to discover that this construction has been used to correct any defect in the eye, or even that a defect similar to that which I have described, has ever been noticed." Thus Airy appears to have been unfamiliar with the observation made forty years earlier by Thomas Young.

How many recognized cases of this sort escaped notice in the medical literature, or in that part of it which has been accessible to me, I cannot say. Under the head of "Particular kinds of nervous affections," the first edition, 1833, of "A treatise on diseases of the eye," by the British surgeon William Lawrence,¹⁷ mentions nearsightedness and farsightedness but makes absolutely no reference to astigmatism. An American edition of Lawrence's work, edited in 1854 by Isaac Hays, Surgeon to Wills Hospital, quotes at length the account by an American clergyman of his own case of astigmatism, which is said to have been corrected with lenses furnished by a Philadelphia optician named McAllister.

In these early cases the estimation of the meridians of astigmatism seems to have been arrived at by the simple expedient of discovering the direction of distortion of the image of a light seen through a small hole in a black card. One supposes that the conclusions as to the meridian or axis, and as to amount of cylinder, may have been somewhat crude.

The section of abstracts of communications to the British Association for the Advancement of Science for the year 1849 contains a brief communication²¹ by Professor Stokes, the well-known mathematician and physicist, "On a mode of measuring astigmatism in a defective eye." This ingenious device, which may to some extent be regarded as the basis of the Jackson cross-cylinder test

for the amount of astigmatism, is described in the following terms: "If two planocylindrical lenses of equal radius, one concave and the other convex, be fixed one in the lid and the other in the body of a small round wooden box, with a hole in the top and bottom, so as to be as nearly as possible in contact, the lenses will neutralize each other when the axes of the surfaces are parallel; and, by merely turning the lid round, an astigmatic lens may be formed of a power varying continuously from zero to twice the astigmatic power of either lens. When a person who has the defect in question has turned the lid till the power suits his eye, an extremely simple numerical calculation, the data for which are furnished by the chord of double the angle through which the lid has been turned, enables him to calculate the curvature of the cylindrical surface of a lens for a pair of spectacles that will correct the defect of his eye."

One form of the Stokes lens is depicted on page 486 of the English edition of Donders. At the 1887 meeting of the American Ophthalmological Society, held in New London, Connecticut, W. F. Dennett³ of New York described and illustrated a special form of the Stokes lens, intended for mounting in a trial frame, and designed to permit not merely of variation in the strength of the cylinder but of adjustment of its principal meridians to any position in the trial frame. Dennett's introductory paragraph seems worth quoting. He says: "The Stokes lens seems hitherto to have been possessed of some intangible and unattainable value, as an astigmometer. There are at least four different instruments, the independent inventions of as many different men, in which this lens is the principal factor, but up to the present time it has ranked as little better than an interesting toy."

It is advisable to repeat and to emphasize that the Stokes lens served merely to give an approximate measurement of well-marked astigmatic errors, upon the basis of an axis previously established by other means, or sometimes by turning of the whole apparatus in the hand of the patient or observer.

In the course of the present address, further reference will be made to Jackson's teachings with regard to cross, or crossed, cylinders. But it may be observed at this point that his work in this field is typical of Jackson's general relation to medical science. To very few medical workers is given the privilege of offering to the world something completely new. In fact, it may be said without contradiction that every new thought or invention is based upon the sum total of previous human knowledge in the given field. But Jackson surveyed every department of his chosen work with penetration and insight and with unremitting labor; and in several phases of refraction work, including the measurement of astigmatism with cross cylinders, he made important refinements and improvements upon what had been proposed by others.

The period of greatest advance in measurement of the refraction of human eyes will be forever associated with the name of F. C. Donders. This clinician's researches at the University of Utrecht led to his publishing in 1860, in the Dutch language, an essay upon "Ametropia and its results" (*Ametropie en Hare Gevolgen*). In the preface to that work the author announced his intention of producing a complete system of the anomalies of refraction and accommodation, including the subject of astigmatism. A little later Donders was requested by the New Sydenham Society, of England, to prepare his essay for an English edition. He responded with a treatise of about six hundred pages in which the whole sub-

ject was exhaustively covered. The manuscript was ably translated by William Daniel Moore of Dublin.

Since the time of Donders, differences of opinion and changes of technique have developed; but as to essentials it is difficult to find any branch of the subject that is not included in the scope of Donders's thought and experience. His volume even has something to say about aniseikonia, although not under that title. Some years ago I ran across a statement that biastigmatism, or the occurrence of distinct and usually conflicting astigmatisms in the cornea and the crystalline lens of the same eye, had been first discovered in or about 1909. I had little difficulty in confirming my suspicion that Donders had clearly referred to this phenomenon in 1864 in his work on accommodation and refraction. He also quite correctly pointed out that bicylindrical lenses, with intersecting axes, could always be advantageously replaced by spherocylindricals.

You will remember that Jackson's brief period of practice of general medicine was cut short by an attack of diphtheria which was followed by many months of incapacity from postdiphtheric paralysis involving the leg muscles and ocular accommodation. It was during this spell of physical incapacity that he familiarized himself "through and through" with Donders's epoch-making working.

What contrasts may we find between refraction before and after Donders? Or again, what changes did the refractive technique of Jackson's active years show in comparison with the precepts laid down by the Dutch teacher?

In the field of ophthalmology, the textbook of William Mackenzie¹⁸ seems to have filled, for many years, much the same authoritative and universal position as has been occupied in modern times by William Osler's "Practice of medicine."

Mackenzie was "Lecturer on the Eye in the University of Glasgow, and one of the surgeons of the Glasgow Eye Infirmary"; later "Surgeon-Oculist in Scotland to her Majesty" Queen Victoria.

Mackenzie's first edition was published in England in 1830. A first American edition, containing 719 pages, appeared in 1833. The fourth American edition, published in Philadelphia in 1855, had 1,027 pages of larger size.

It is not altogether surprising that the 1833 and the 1855 editions of Mackenzie's treatise devoted extremely little space to refractive errors. Even in the fourth edition, asthenopia, considered as a disease, was attributed to many causes, among which refractive error fails to be included. Myopia and presbyopia were contrasted as two opposite conditions, approximately as myopia and hyperopia are contrasted today. We are, however, told that "young men of twenty sometimes cannot see to read or write without convex glasses of six or eight inches focus."

As to astigmatism, the earlier English edition of Mackenzie is silent. In the 1855 American edition, the two-and-a-half pages devoted to an explanation of astigmatism are chiefly occupied with a record of the famous case of the astronomer Airy. Mention is made of the clergyman Whewell's proposal of the word "astigmatism," also of the several cases which had been published in the literature, and of the Stokes lens.

Speaking in 1833 of "presbyopia or farsightedness," the English surgeon and ophthalmologist Lawrence advises that glasses for its correction "must be chosen . . ." so as to "enable the person to see without straining or fatiguing the organ, and should only be worn for reading, writing, or examination of near objects."

By both Mackenzie and Lawrence a good deal of space was devoted to dis-

cussion of asthenopia and theories as to its causation. Mackenzie was quite pessimistic on the subject. "In many cases," he said, "it is our duty to declare the disease incurable. . . . Many a poor man have I told to give up a sedentary trade, and drive a horse and cart; while to those in better circumstances, and not far advanced in life, I have recommended emigration. . . ."

Donders, commenting on some further remarks by Mackenzie, says: "There is no doubt that Mackenzie gave far too weak glasses." While admitting that many other conditions had often been mistaken for asthenopia, Donders boldly asserted that the cause of "the pure form of asthenopia" lay in hyperopia, and that asthenopia was not the fatigue associated with looking at other objects, but the want of power through which the fatigue occurred.

Reference may be made to what Donders stigmatizes as "a melancholy page in the history of operative ophthalmic surgery," the fact that certain practitioners, attributing asthenopia to spastic contraction of external eye muscles, "had the courage to cut through the muscles." This practice Donders justifiably characterizes as belonging "to the fables of the period of operative mania."

The correction of myopia with spectacles is usually thought of as a rather simple matter. In earlier times, its understanding and the practical results obtained were commonly much complicated by complete, or almost complete, ignorance regarding astigmatism, since the myopic eye with an appreciable amount of astigmatism could not be perfectly corrected with a simple concave sphere.

We find Lawrence, in 1833, advising his readers that "from the use, under proper precautions, of such concave glasses as will rectify the error in the refractive power, the nearsighted person

need not apprehend any injury to the eye; indeed, the easy exercise of vision with the recognized optical aid, seems to me less hurtful than the straining and efforts to do without it." But he adds: "As there is some reason for concluding that the optical powers accommodate themselves to the circumstances under which vision is habitually exercised, I recommend nearsighted persons not to wear spectacles constantly. . . ."

Since in 1854 the American edition of Lawrence quotes at a good deal of length from Mackenzie's discussion of refraction, the latter British writer may probably be considered typical of opinion in Great Britain and America at the middle of the nineteenth century. For the myopic patient Mackenzie recommends "frequent exercise out of doors, walking and riding in the country, and travelling through new and interesting scenes." "If," he says, "instead of such a plan of conduct, recourse be had to the employment of concave glasses, and the frequent and long-continued observation of near objects be persisted in, the disease becomes not only confirmed but sometimes greatly aggravated. . . . We must recommend to the nearsighted person to be content with the shallowest glasses or lowest number which answers his purpose. . . . When a nearsighted person wishes to be fitted with concave glasses, the simplest and shortest plan is to try a series of them at an optician's shop. . . . If the nearsighted person is desirous of assistance in seeing remote objects . . . the focal distance of the glasses . . . should be the distance at which a small object appears distinct to his naked eye. For example, if he reads this type at 12 inches distance, 12 inches will be the focus of the concave glasses which he will require for seeing distant objects distinctly."

Hays, the American editor of Lawrence's fourth edition, has progressed to

the point of declaring that "presbyopia is not a defect of old age alone, it occurs also in young persons; and, if we may judge from the number of examples of this which have come under our observation, much more frequently than is generally supposed." A footnote to the same chapter states that "convex glasses are kept in the shops of every focal length, from forty-eight inches to six."

Donders clearly stated the refraction of the eye to be its refraction in the state of rest, "independently of accommodation . . . for example under the influence of atropine."

By the time Donders's volume was written he had the benefit of a few years of experience in the truths revealed by the ophthalmoscope. To him, the prescribing of spectacles had become a part of ophthalmic surgery. He tells us about refraction with the ophthalmoscope. He still used the inch system for numbering the focus of spectacle lenses. He speaks of a former belief that myopia was the normal condition of the human eye, and states that hyperopia had been "until quite recently almost entirely overlooked, at least its nature and results were not recognized. But once discovered and understood," he says, "it speedily revealed all its mysteries, and gave us the key to a number of phenomena. . . . Thus the source of asthenopia and of strabismus convergens was found in this anomaly."

Donders's preliminary estimate of the amount of myopic correction required was made by placing in the hand of the patient a book with small type, with which the patient was to indicate his farthest point of distinct vision. The patient was then to remove the book a little farther until the letters were rather less distinct. But Donders warns that "experience has taught me that we cannot be too cautious, for with good accommoda-

tion the action of too strong glasses is easily enough overcome. . . ."

We find in Donders several evidences of a prejudice against what the author calls "complete neutralization of myopia," in other words its complete correction. This is hardly surprising when we remember that probably most of the myopic patients had uncorrected astigmatism which easily became a source of eyestrain. Thus we are told that in certain cases the use of glasses is dangerous "and must be discontinued, so soon as it appears that the myopia is particularly progressive." Again, "in very slight degrees, from $1/60$ to $1/18$ " [that is, from about $2/3$ to 2.25 diopters] "we may leave the myope to himself." Further, "in the higher degrees, from $1/5$ " [that is, 8 diopters] "upwards, perfect neutralization is not pleasant for close work because . . . the images become too small." In such cases Donders would correct 3.25 to 2.50D., wearing for distant vision a lorgnette held before the spectacles. He remarks that the idea that there is anything injurious in this combination is an unfounded prejudice.

Even today in the United States it is still customary with some ophthalmologists to undercorrect myopia in the fear of throwing an excessive strain upon the patient's accommodation, and I believe I am right in saying that this tendency is carried much further in most European countries than in our own.

In the study of hyperopia, Donders, like many modern workers, was much disconcerted by the problem of latent hyperopia. He says: "In my first investigations respecting H, I encountered the difficulty of accurately determining the degree of this anomaly . . . I assumed that hypermetropic eyes, obliged to put their power of accommodation upon the stretch in order to see remote objects,

sometimes involuntarily to a certain degree kept up the tension, even when the proper glasses rendered this not only superfluous, but undesirable for accurate vision. Therefore, from the strongest glasses, with which the eye had, at different trials, still seen accurately at a distance, the degree of H was reduced. This should, as I supposed, completely neutralize the H. But when shortly afterwards, still stronger glasses were sometimes found adapted to the same persons, I discovered my error, and comprehended that those first given had not completely neutralized the H, and that in using them the accommodation to a certain degree continued in operation." Thus Donders was led to study the situation under atropine, and to his surprise found that not infrequently the greater part of the H had been suppressed. This led to the discovery that moderate degrees of H might be wholly suppressed, especially in cases of asthenopia and strabismus.

In this connection two comments seem to be called for. In the first place the examination for hyperopia, in Donders's days, must have been complicated by the fact that Snellen's recently introduced form of letter chart had not yet been generally adopted, and that it was still a very usual custom to measure the patient's far point by varying the distance of test letters from the patient, instead of depending upon variations in size of letters read at a fixed distance. The second comment is that in the earlier literature I have been unable to find any reference to the fogging method, and especially to bilateral fogging, by means of which it is now possible in most cases to uncover approximately the whole hyperopic error before using cycloplegia.

As regards the former observation, it is peculiarly interesting to note that the custom of three quarters of a century ago

is persisted in by one of our most useful and necessary public institutions, the United States Navy, which still measures the distance at which the patient or candidate can recognize certain letters or signs, instead of having him read progressively smaller letters on a Snellen chart at a fixed and remote distance. It is true that the visual standards in the Navy lessen the harmfulness of this antiquated method, which in ordinary practice would have the substantial disadvantage of ignoring the influence of uncorrected myopia upon the statements of visual acuity.

It was the remarkable practice of a number of writers before Donders to treat asthenopia by first prescribing convex lenses and then, after an interval in which the patient was denied the use of his accommodation in close work, to weaken the spectacles gradually, and at the same time to permit gradually increasing application to close work. We cannot but agree with Donders's skepticism as to the success of such a course of treatment. And it is no wonder that, as we have seen, Mackenzie admitted he found it his duty in many instances to declare the asthenopia incurable!

Thus, as to the three great factors in refraction work, we see that Donders's attitudes were as follows: In myopia he was generally averse to full correction. In hyperopia he had made some steps toward recognizing the need for full correction, so far as near work was concerned, but hesitated to ask the patient to wear his correction for distant vision. As regards astigmatism, he was still using methods of measurement which were primitive as compared with those available today, and he hardly recognized the necessity for correcting astigmatism of less than one diopter. Since amounts of astigmatism which we now regard as significant enter into the correction of most

cases of hyperopia and myopia, we can see that the great majority of patients suffering from visual defects correctable by glasses either were given inadequate correction or failed to obtain any.

Since about fifteen years elapsed between the publication of Donders's work in English by the New Sydenham Society and Jackson's entry into practical ophthalmology, it is obvious that a good many American professional men must have studied the problems of refraction before Jackson's light began to shine. Noteworthy among these are H. Derby,⁴ of Boston, and the elder John Green,⁶ of Saint Louis. The latter showed a very special interest in tests for astigmatism.

In 1867 Green published in the *American Journal of the Medical Sciences* an excellent paper entitled "Detection and measurement of astigmatism," with illustrations of three astigmatic dials of his own design. One of these had sixty radiating lines whose selection was aided by Roman numerals corresponding to the hours of the clock.

Jackson's important contributions to the art of refraction may be practically divided into two groups, the one dealing with the principles upon which refractive corrections were to be measured and prescribed, the other concerned with improvements in technique.

As regards principle, the Jackson of the early eighties naturally began at the stage of development which had been reached by teachers and colleagues, the most important of the former being Donders. But, as Jackson carried on the practice of ophthalmology in the clinic and in his private office, he tended to investigate for himself the principles laid down by others, and to discover where these principles were faulty or incomplete.

It is unfortunate that history cannot record the lively interchange of ideas

and experiences which must have gone on between the ophthalmologists of those years, particularly in Philadelphia.

The basis of Jackson's attitude toward correction of myopia and hyperopia is expressed in several papers. One of these,⁸ "The full correction of ametropia," was read in 1891 before the Section on Ophthalmology of the American Medical Association; the other,⁹ "The full correction of myopia," in 1892 before the American Ophthalmological Society. We find Jackson's logical mind impressed by the fact that the emmetropic eye is generally thought of as the ideal eye, and that "when an ametropic eye suffers from strain, one of the most important things that can be done for it . . . is to give it the optical aids that will make the conditions under which it works more nearly approach those of the emmetropic eye."

The fact that many of his colleagues did not follow this logical train of thought to its legitimate results was attributed by Jackson to several reasons. The first was that the new conditions caused by the wearing of correcting lenses always required a period of adaptation, particularly as regards the act of binocular vision. But he argued that in the long run, and apart from certain exceptional conditions, this period of adaptation was likely to be less protracted and less annoying when the correction for ametropia was complete than when it was partial. He stated that with due co-operation on the part of the patient he had never seen a case of so-called ciliary spasm that did not yield, so as to allow of perfect distant vision with the total correction, within two months of constant wearing of the glasses, and only two such cases that did not yield within two weeks.

However, and here is a point with re-

gard to which the textbooks are still generally at fault, the Jackson of 1891 points out that "the best correction at 4 or 6 meters is not the correcting glass for the total H., but is an overcorrection of $1/4$ or $1/6$ D."; continuing: "I know of no treatise on this subject that takes this into account." The practical significance of this fact is, of course, that, using Jackson's words, "patients given a 0.25D. overcorrection will not become accustomed to it and see clearly at a distance in any length of time. This inaccuracy must be avoided if you are going to correct the total H." Other conditions to which Jackson then called attention as affecting the result are the aberration of the eye and the necessity for fully warning the patient in advance of the early difficulties he may experience.

As to myopia, the Jackson of 1891 was merely one of a number of ophthalmologists who had reached the conclusion that it was usually preferable to give full correction for myopia. One of his colleagues, George C. Harlan of Philadelphia, who discussed the subject in a separate paper,⁷ speaks of being encouraged to bring up the topic by Jackson's "temerity" in dealing with so trite a subject; and this suggests the comment that Jackson never hesitated to bring up a subject which some might think trite, but in regard to which many misconceptions and superstitions still existed among the profession.

Harlan's paper recalled how at the International Congress in New York, in 1876, a member had inquired concerning the practice of his colleagues as to the constant correction of myopia, and that a youthful ophthalmologist had been heard to mutter contemptuously, "Why does he take the time of the Congress with that? Why don't he read his textbook?" And Harlan remarked that that

was probably just what the inquirer had been doing, and that it was the unsatisfactory result of this investigation that led to the question!

Jackson asserted that, contrary to many previous statements, he and others had more recently convinced themselves that the power of accommodation was usually as great in myopes as in hyperopes of the same age. He also called attention to a fact too often overlooked, namely that undercorrection of myopia instead of avoiding eyestrain often induced it, because the undercorrected myopic patient is likely to look obliquely through his lenses in order to increase their effect, and by so doing creates an artificial astigmatism.

Many years later Jackson returned to the same subject in a lecture¹⁰ delivered at the Philadelphia Polyclinic. He here condemns the assumption "that to leave uncorrected a part of the refractive error when prescribing will not seriously lessen the benefit. This assumption," he continues, "involves two errors. First, that all persons can overcome ametropia without feeling worse for it; and second, that the altered ametropia created by a partial correction will be as well tolerated as the same amount of ametropia arising during the development of the eye, and to which the patient has always been accustomed." In this paper Jackson recalls the case of a physician of robust physique, past fifty years of age, "who suffered from dizziness and nervous dyspepsia; and who was only relieved by the constant wearing of his correcting lenses:

R. + 0.37 \subset + 0.25 cy.

L. + 0.25 sph."

Jackson's studious and critical contributions to refractive technique dealt particularly with the relative value of the ophthalmometer, with the principles and practical employment of the shadow test,

and last but not least with the testing of amount and axis of astigmatism by means of the cross cylinder. In 1887 he described his refraction ophthalmoscope,¹¹ but, however convenient within certain limitations the design of this instrument was, the use of the ophthalmoscope for refracting seems never to have established itself very firmly, although much favored by Loring.

Jackson's paper¹² on "The value of the ophthalmometer in practical refraction work," read before the American Ophthalmological Society in 1894, emphasized the fact that this apparatus measured only the corneal astigmatism, and he presented a statistical analysis to show that in three fourths of the cases corneal did not correspond to total astigmatism, that in almost one half of the cases the ophthalmometer was misleading as to the meridians of the total astigmatism, that determination of the direction of the astigmatism with the ophthalmometer was especially apt to be uncertain where the amount of the astigmatism was less than 0.50D., and that as a means of approximating the probable amount and meridians of total astigmatism it was greatly inferior to skiascopy among objective methods, and distinctly inferior to various subjective tests.

Jackson's detailed study of the shadow test,¹³ first published in 1895, is one of the best productions of American ophthalmic literature. He had published two important articles on the subject in 1885 and 1886, the former in the American Journal of the Medical Sciences, the latter in the Journal of the American Medical Association. The shadow test, first described by Cuignet in 1875, had gradually come into use in France and England. But Jackson acknowledged in 1885 that he had been able to find only a single brief and inadequate description of it that had

been published on this side of the Atlantic.

Most advocates of the method had recommended its use with the concave mirror, the concave mirror of the ophthalmoscope being usually employed. Jackson pointed out the distinct disadvantages of the concave and recommended the plane mirror, particularly with a small source of light. Loring had apparently dismissed the method "as of no practical importance."

As already indicated, the cross-cylinder combination referred to earlier in this address as having been devised by the English physicist Stokes, and later modified by Dennett and others, was a rather cumbersome contrivance whose purpose was to make a rapid variation in the amount of cylindrical lens held before the eye.

In 1887 Jackson read¹⁴ before the American Ophthalmological Society a paper describing "a trial set of small lenses and a modified trial-frame." This trial set employed planospherical and plano-cylindrical lenses of 1-inch diameter. In the course of the paper, Jackson included the following paragraph: "Astigmatic lenses have been added. The astigmatic lens, as described by Stokes, has with regard to one axis the action of a concave cylindrical lens; and in regard to the axis perpendicular to the former, the action of a concave cylindrical lens of equal refractive power. Such a lens is made by combining either convex or concave cylindricals, of equal refractive power, with axes perpendicular; or a spherical of one kind with a cylindrical of the other kind of twice the strength. The two used in this case are:

— 0.25 sph. \bigcirc + 0.50 cy.,

and — 0.50 sph. \bigcirc + 1 cy.,

of which the former is most generally useful. For two years I have used such a lens to hold in front of the approximate

correction, to determine if a cylindrical lens or a modification of the cylindrical already chosen will improve it; and it is far more useful, and far more used, than any other one lens in my trial set."

He then went on to describe an illustrative case. His earlier technique seems to have been to revolve the axis of the cross cylinder over a semicircle, and I believe that the only handle possessed by the two cross cylinders mentioned was the sort of handle attached to every other lens in the trial case. No drawings were given in explanation of the lenses and the technique of their use.

E. E. Maddox of Bournemouth, England, gave the cross-cylinder test for amount of astigmatism enthusiastic mention in a volume¹⁹ called "Golden Rules of refraction"; and Schneideman²⁰ of Philadelphia discussed the subject very briefly in 1900. But Jackson made little further reference to it in print until the appearance of a paper¹⁵ read before the Colorado Ophthalmological Society in 1907, under the title "Astigmatic lens (crossed cylinder) to determine amount and meridians of astigmatism."

In that article Jackson gave his first printed account of the axis test with the cross cylinder, with the following introductory remark: "Especially strange does it seem to me that I employed such lenses for twenty years, to estimate the strength of the cylinder, without appreciating their great superiority for fixing the direction of the axis, although for several years I had occasionally employed them for this latter purpose." This article contained a couple of drawings to show the effect of crossing equal and like cylinders with their axes 45 degrees apart.

In my earlier years I had the distinct impression that both cross-cylinder tests, and especially that for the axis of astigmatism, were chiefly used by the relative-

ly few who had had the benefit of direct personal demonstration by Jackson. It was this impression, and experience in teaching the test during the Summer Course in Ophthalmology which Jackson had initiated in connection with the Colorado Ophthalmological Society, which led me to present my photographic demonstration before the International Congress of Ophthalmology in Washington in 1922.

The papers I have mentioned seem to me the most significant of Jackson's writings regarding refraction. There were many others, chief of them perhaps one read before the American Ophthalmological Society in 1888, "Symmetrical aberration of the eye,"¹⁶ that is, the variations in curvature which occur, not as between meridians, but from center to periphery. Jackson had at first called the condition "meridional astigmatism," but the expression was properly criticized by Burnett and the elder John Green as likely to lead to confusion. This condition, Jackson's paper points out, is extremely important in regard to the technique and reliability or otherwise of skiascopy, as to some of the differences between refraction without and with cycloplegia, and as to the patients in whom it seems absolutely impossible to secure definite and consistent results concerning refractive measurement.

I have been disposed to think that Jackson displayed rather scant appreciation of the value of the better sort of astigmatic dials, the technique of which has been so ably elaborated by Lancaster and others. I believe, however, that he did occasionally use such dials in his own office practice.

The philosophy of Jackson's teachings with regard to refraction was built upon his conception of the importance of refractive measurement in the life of the

citizen, upon the belief that emmetropia was the goal to be sought in prescribing the distant correction, and upon the need for the utmost possible precision in the work of the refracting ophthalmologist, both in the interest of the patient and in the interest of the profession. His well-known activities in the direction of standardization of education for ophthalmic practice have been reviewed elsewhere.²

He always placed his sense of duty as a teacher ahead of the demands of daily practice. He personified the thought that the value of a man's life does not lie in the extent of his financial accumulations but in the knowledge of work well done, of lessons well learned and handed on to others, in the richness of his experience and the sincerity of his purpose.

MYASTHENIA GRAVIS AND ITS OCULAR SIGNS: A REVIEW*

FRANK B. WALSH, M.D.

Baltimore, Maryland

The primary purpose of this paper is to evaluate our present state of knowledge regarding the ocular signs of myasthenia gravis. However, it is quite impossible to appreciate the ocular symptomatology without having a general knowledge of the disease and of its treatment, for this is one disease in which diagnosis and treatment are largely dependent upon the use of a single drug, *prostigmine*.

I. GENERAL REVIEW

Pathology. Since Weigert's original description of collections of lymphoid cells in the muscles and changes in the thymus, relatively little has been added to our knowledge of the pathology (figs. 1, 2, 3, 4).

Collections of lymphoid cells in the muscles or the absence of such cells does not indicate the severity of the affection. Buzzard termed these cell accumulations "lymphorrhages," and this term has come into general use. We have observed cases in which lymphorrhages were numerous and others in which they occurred in some sections of the muscles but not in others. It seems altogether likely that in any case of myasthenia gravis if a sufficient number of sections are examined, some of these cell nests may be found between the muscle fibers and around the blood

vessels. In addition they may be found in the heart, liver, endocrine glands, salivary glands, and lungs (Wilson). According to Rottino and others myocarditis may be part of the pathology of myasthenia gravis. Their case exhibited areas of necrosis with secondary inflammatory changes in the heart, a finding described as entirely unlike lymphoid-cell infiltration.

Myasthenic muscles may undergo slight changes in the increase of sarcolemma nuclei, fatty infiltration, hyaloid appearance, or, according to Wilson, the muscles may become small and pale. Whether or not structural changes amounting to complete atrophy occur is a point on which there is not general agreement, but if so pronounced a change does occur, it might well be observed in the ocular muscles.

As regards the thymus in myasthenia gravis, it has been known for a long time that thymus tumor may be associated with the disease, or that there may be hypertrophy of the thymus gland. Thus, Bell, in 56 autopsied cases, found that the gland was hypertrophied in 17 and that tumor was present in 10 instances. From such reports it was reasonable to assume that thymus changes were significant only when tumor or hypertrophy of the gland was present. Recent observations by Blackman and by Sloan seem to establish as constant, changes in the thymus even when there is pronounced and normal involution of the gland. These changes consist of an infiltration of the medulla with lymphocytes and an increase in the relative width of the cortex, which becomes packed with lymphoid cells. The differentiation between the cortex and the medulla of the gland is lost. Lymphoid

This paper has been based on case reports and these and parts of the text which have been deleted may be found in the Transactions of the American Ophthalmological Society of 1943.

Fig. 1 (Walsh). Section of muscle showing collection of lymphocytes (Aut. 17768).

Fig. 2 (Walsh). Thymus tumor (high power). The section shows cells of two types: (1) smaller lymphocytes; (2) sheets of large epithelial cells. In general the proportions of these cells vary. The division into lobules separated by fibrous septa is not shown (Aut 17768).

follicles with germinal centers are present in the medulla.

Sloan examined the thymus in cases of Addison's disease, acromegaly, and hyperthyroidism. In three of seven cases

of Addison's disease, and in two of five cases of acromegaly, the histologic picture was similar to that seen in myasthenia gravis. In 20 thymus glands removed from individuals with hyperthyroidism

Fig. 3 (Walsh). A metastasis. Metastases are the same as the primary tumor, but often contain large channels filled with blood. Such channels are sometimes present to a less degree in primary tumor of the thymus. In this case the metastases were present in the visceral and parietal pleura of only one side.

Fig. 4 (Walsh). Hyperplasia of the thymus. Note the pronounced hyperplasia of the cortex and the presence of many germinal centers.

there was lack of involution in 18 cases, and in the remaining five the changes were similar to those seen in myasthenia gravis.

In the central nervous system, in a

great majority of cases, there is no involvement. McAlpine has described slight lymphocytosis in the brain stem, with perivascular infiltration and hemorrhages into the gray matter. He suggested that

these findings pointed to an occasional relationship between myasthenia gravis and epidemic encephalitis.

Occurrence. That myasthenia gravis is not a rare disease is evidenced by the number of cases which form the basis for this report. Before prostigmine became available, the diagnosis was frequently missed. Thus Viets remarked that in the Massachusetts General Hospital up to 1935 the diagnosis of myasthenia gravis was made about once a year, whereas from 1934 to 1941, 84 cases were so diagnosed. Our experience in the Johns Hopkins Hospital has been similar.

The sexes are about equally affected. In the series reported here there were 27 males and 36 females, and of these, 50 were white and 13 were colored. There were 22 white males and 28 white females, 5 colored males and 8 colored females. As regards the age incidence, the earliest age of onset was 11 months and the oldest age at onset of the disease was 75 years. The occurrence according to decades was: 0 to 10 years, 5 cases; 10 to 20 years, 10 cases; 20 to 30 years, 13 cases; 30 to 40 years, 19 cases; 40 to 50 years, 5 cases; 50 to 60 years, 7 cases; 60 to 70 years, 3 cases; 70 to 80 years, 1 case.

Heredity rarely appears to play a role, and no example was recorded among our cases. Noyes has reported the affection in a father and two daughters, Marinesco in two sisters, Hart in two siblings, and Rothbart in four brothers of a family.

The occurrence of myasthenia gravis in infancy and early childhood has always been questioned (by Kinnier Wilson among others). Consequently the observation of five cases in children below 10 years of age merits particular attention. Four of these five cases were in Negro children under six years of age. It is interesting to note that the affection may begin at as early an age as 11 months.

Booth (1908) recorded a case at 23 months, and Kawaichi and Ito (1942) one at 21 months. It seems remarkable that it may begin at the age of 75 years, as in Case 61, where the diagnosis was established when the patient was 82 years old.

Contributing factors. It is impossible completely to evaluate exciting or contributing factors, since we do not know the etiology of the disease. There can be no doubt regarding the frequency with which the affection first manifests itself after a respiratory infection, since exacerbations are commonly observed as the result of such infections. The onset may be influenced by normal labor; its course may be affected by pregnancy, usually favorably (Viets and others), but not always so. Myasthenia gravis does not interfere with normal labor (Laurent). We have observed the development of myasthenia after ptomaine poisoning, after severe dog bites, and in association with urticaria.

In a great majority of cases there does not seem to be any exciting or contributing factor.

Associated conditions. Hysteria or emotional outbursts have been mentioned in several cases that have come under our observation. We have seen it in patients who exhibited signs of hyperthyroidism; in another patient who exhibited exophthalmos in the absence of signs of hyperthyroidism, and in association with diabetes. In one case there was evidence of the previous existence of anterior poliomyelitis or of some other disorder responsible for the smallness of one limb.

Curschmann reviewed particularly the possible role of the ductless glands in the production of myasthenia gravis, and concluded that in all probability endocrine disturbances were incidental rather than causative. He included congenital defects occurring in myasthenics, and observed it in two cases of aplasia of the female

genitals. He referred to the possible relationship of hyperthyroidism to myasthenia gravis, and was unable to obtain a myasthenic reaction in very severe cases of hyperthyroidism. Curschmann remarked that Marinesco had described hyperplasia of the hypophysis, and Tilney reported adenoma of the hypophysis in cases of myasthenia gravis.

Etiology. The nature of the fundamental disturbances responsible for myasthenia gravis is not known. All the available evidence, both clinical and experimental, points to the defect being in the muscles, and to the neuromuscular junction as the site of the disturbance. The evidence is necessarily incomplete and selective, since the literature is enormous and contains conflicting reports and complicated hypotheses.

Probably the earliest, and certainly one of the most productive, discoveries was made by Claude Bernard in 1857, when he found that mild curare poisoning will block impulses passing from nerve to muscle when both are capable of functioning. Because Walker recognized a similarity between paralyses of mild curare poisoning, and those of myasthenia gravis, eserine was used in the treatment of myasthenia gravis, since it was known to be a decurarizing agent.

Recently acquired knowledge which has an important bearing on the problem concerns the chemical transmission of nerve impulses (Dale, Cannon, and Rosenblueth among others). This work requires only brief mention here. It has been established that in the autonomic system there are chemical transmitter substances, acetylcholine and sympathin. It has been assumed that acetylcholine is the transmitter substance responsible for the contraction of skeletal muscle, and this has been substantiated, in part at least, by the finding of acetylcholine in eserinizied perfusion fluid from skeletal muscles when

the motor nerve has been stimulated (Dale and Feldberg). As Dale has remarked, if acetylcholine is the chemical mediator which acts as a direct excitator of skeletal muscle fibers, it would have to appear with flashlike suddenness when an impulse reaches the motor nerve endings; then it would have to disappear within the brief span of the refractory period. It seems proved that eserine has a protective influence on acetylcholine through rapidly breaking down cholinesterases which hydrolyze acetylcholine. Prostigmine, a substance closely related to eserine, has been found to be more effective than the latter in the treatment of myasthenia gravis. However, as regards the action of eserine, it has not been established that it acts entirely by attacking the cholinesterases, and it has been found that it is capable of stimulating motor nerve endings; it has also been determined that cholinesterases are normal in myasthenia gravis (Jones and Stadie).

To continue with the evidence which seems to point to the causal factor of myasthenia gravis being associated with abnormality at the neuromuscular junction, there may now be considered the clinical effects of prostigmine, acetylcholine, and other substances in normal individuals and in those suffering from myasthenia gravis.

When injected into the brachial artery of normal individuals in amounts of 0.5 to 1.5 mg., prostigmine produces: (1) a profound paresis of the muscles in the injected extremity (a band is placed about the arm in order to make the injection); (2) fasciculations (twitchings, fibrillations) of the muscle fibers in the extremity and similar but less pronounced twitchings elsewhere after the tourniquet has been removed. Prostigmine similarly injected into the brachial artery or elsewhere in a person suffering from myasthenia gravis gives precisely opposite re-

sults; namely, (1) partial or complete return of motor power; (2) no fasciculations.

Acetylcholine when injected intra-arterially in amounts of 20 to 40 mg. in normal individuals produces transient weakness of the extremity. If injected into an individual with myasthenia gravis, it produces a sudden contraction of the injected muscles.

Quinine, a curarizing agent, when given to normal individuals, produces no change in muscle response. If given to an individual suffering from myasthenia gravis, there is a pronounced increase in the weakness of the affected muscles (Harvey and Whitehill). An exception to this generalization may have been observed in case 12, where only the ocular muscles were involved. This case has possible significance from the standpoint of myasthenia gravis in some instances affecting only the ocular muscles. It is further considered in part II.

Other substances which are said to have a decurarizing effect are potassium chloride, guanidine, and calcium chloride. The administration of these substances to individuals suffering from myasthenia gravis does not produce detectable changes (Harvey and Whitehill).

Much experimental work has been done in recording the effects of stimulation of muscles. The electromyograms of normal individuals have been compared with those of individuals suffering from myasthenia gravis both before and after the administration of various drugs.

In normal muscles, Cobb and his collaborators confirmed previous work showing that the frequency of the primary waves during contraction diminished from 40 to 60 per second, but that the amplitude increased; and that in myasthenic muscles the frequency did not diminish, but the amplitude was smaller at the beginning than in normal muscles and

rapidly diminished. These investigators observed that myasthenic muscle loses its contractile power before the onset of fatigue. Lindsley found that after intramuscular injection of prostigmine the myographic curves became practically normal. Harvey and Masland noted that the action potential recorded from the muscle of an individual suffering from myasthenia gravis was the same as that obtained from a normal individual when a single stimulus was applied. When responses to paired stimuli were compared, it became apparent that the response to the second stimulation was often smaller than that to the first, whereas in normal individuals there was no such difference. When the nerve was stimulated at low frequencies (50 per second or less), the muscle action potentials showed a rapid decline in voltage during the first few responses and then continued at lower levels of response. However, in normal individuals the muscle potentials showed little change.

From figure 5 it may be seen that following the administration of prostigmine the muscle action potentials became approximately normal. Harvey and Masland found increased abnormalities in myasthenics after the administration of quinine, but discovered that potassium chloride, guanidine, calcium chloride, and vitamin B₆ did not influence the electromyograms of individuals suffering from myasthenia gravis.

Harvey, Lilienthal, and Talbot studied five patients who had been subjected to thymectomy for the treatment of myasthenia gravis. They observed fasciculations in the muscles of three of these patients after the intra-arterial injection of prostigmine, and all three developed local paresis just as occurs in normal individuals. In these patients, all of whom had been favorably influenced by the operation, electromyograms showed that a large

number of muscle fibers responded and that there was greater efficiency in the transmission of pairs and trains of maximal motor-nerve stimuli.

Largely on the basis of the observations just mentioned, Harvey, Lilienthal, and Talbot concluded that in myasthenia gravis there is a deficiency of acetylcholine at the neuromuscular junction. This, in their opinion, accounts for the characteristic changes which they found in electromyograms. Their arguments were set forth as follows: (1) Prostigmine has a protective influence upon acetylcholine. (2) In normal individuals the injection of prostigmine intra-arterially produces local paralysis, and a similar result occurs from the injection of acetylcholine. Since precisely opposite results are obtained from the same procedures in patients with myasthenia gravis, it seems to follow that there is an insufficient amount of acetylcholine to provide for a depressant action. (Case 3 exemplifies such an unfavorable influence from the injection of prostigmine in an individual with myasthenia gravis. In this case large doses produced general toxic effects but increased the range of the ocular movements which had not been influenced by average doses.) (3) Finally, Harvey and his collaborators drew upon Cannon's theory of sensitization to a transmitter substance and assumed that if less acetylcholine is available, the threshold of the muscle for this substance is lowered.

The conclusions of Harvey and his collaborators seem to fit reasonably the facts so far as we know them, but they are, in part at least, based upon hypotheses which have not been completely verified. Many problems require more convincing proof than that available from the translation of electromyograms. It has previously been stated that there is some proof that acetylcholine is the transmitter substance responsible for the mediation of motor-

nerve impulses to skeletal muscles. However, other mechanisms may play a part in the transmission of such impulses. It has been observed that the intravenous injection of acetylcholine may produce slow tonic contractions of skeletal muscle (Bard), and it was maintained by Duke-Elder and Duke-Elder that there was likely to be selective involvement of the muscles attached to the eyeballs. This is difficult to understand if the skeletal muscles normally contract as the result of the flashlike appearance of acetylcholine, as suggested by Dale.

Furthermore, if the extraocular muscles are as sensitive to acetylcholine as Duke-Elder's observations imply, it is difficult to understand why these muscles, with the exception of the levator palpebrae, are particularly resistant to prostigmine in individuals suffering from myasthenia gravis.

GENERAL SYMPTOMATOLOGY

Myasthenia gravis is characterized by fatigability and weakness of the muscles. It is difficult, if not impossible, to prove that fatigability precedes weakness, but it seems probable that it does. The diagnosis rests essentially upon the demonstration of fatigability. Usually this is readily accomplished in individuals suffering from myasthenia gravis by repeated opening and closing of the eyes or mouth, counting aloud, opening and closing the hand, raising the leg, or other similar movements intended to tire the affected muscles. As a rule, the diagnosis is made easily, but in some cases it may be difficult to make.

Ocular symptoms and signs. In all cases in this series there were ocular symptoms or signs, and these were usually the earliest manifestations of the affection.

Diplopia is frequently the earliest symptom of the disease. It may be present where there is no visible evidence of

limitation of ocular movements, or it may be associated with ptosis or with muscle paresis. Ptosis, often bilateral, occurs frequently. Characteristically, it is absent or minimal in the morning, becoming more pronounced as the patient becomes fatigued. Limitation of ocular movements varies within wide limits, and often affects both eyes, but may affect only one eye or even a single muscle. Inability to close the eyelids tightly is frequently present; it may be associated with ptosis and with limitation of ocular movements. The ability to converge the eyes is often lost. In our experience, the pupils are not affected in myasthenia gravis. The visual acuity and visual fields are not altered. It seems highly questionable whether accommodation deficits can properly be attributed to myasthenia gravis.

"Bulbar" signs. Early writers referred to myasthenia gravis as asthenic bulbar paralysis (Strümpell) because of the following signs: Facial weakness, usually bilateral, is commonly present and was observed in 23 cases. This weakness lends a flat appearance to the face, and a smile seems more like a snarl, since the retractor muscles at the corners of the mouth are more severely affected than the elevators. Facial weakness is often associated with inability to close the eyelids tightly and with ptosis and paralyzes of the extraocular muscles.

Weakness of the jaw muscles, which was present in 10 cases, accounts for the inability to chew food properly, and often develops toward the end of a meal. In severe cases the lower jaw sags and can be elevated only by the aid of the hands. We observed a myasthenic who placed a rubber band around his head and jaw to keep the latter in position.

Weakness of the soft palate and pharynx produces difficulty or inability to swallow properly. In severe cases regurgitation of fluids through the nose occurs

(10 cases). Palatal weakness lends a nasal quality to the voice, which is readily demonstrated by asking the patient to count aloud. Weakness of the tongue and larynx adds to the difficulty in speaking, and if the laryngeal muscles are severely affected there is aphonia.

Weakness of the intercostal muscles and diaphragm is responsible for dyspnea and varies according to the amount of rest the myasthenic has had. In severe cases periods of respiratory distress come on, at first after tiring, later appearing spontaneously and without apparent cause. Occasionally respiratory distress is apoplectic in its onset, and respiratory failure is a common cause of death in myasthenia gravis.

Other signs. Weakness of the muscles of the legs and arms may be the earliest evidence of the disease, and in our experience this weakness of the legs is fairly often an early manifestation of myasthenia gravis. The hands and arms may become weak or powerless after use; such weakness was observed as an early sign in case 63. There may be complaints of weakness only in one arm, or only of the fingers. Women often complain of tiring of the arms when combing their hair. The weakness may appear to be bilaterally selective, as shown in case 33, in which the first symptom was weakness of the ring and little fingers of both hands. Weakness of the muscles of the neck is a frequent sign. On becoming fatigued the patient is unable to hold the head erect and must support it with the hands.

Other body muscles, such as those of the spine and abdomen, may be involved. In such cases the patient is unable to sit in a chair for more than a few minutes, and in the few bedridden individuals whom we have observed there have invariably been many evidences of the disease.

Muscular wasting is not commonly

present, and in severe cases, according to our experience, it is not pronounced. Whether profound myasthenia gravis may result in permanent paralysis is open to question, but Collier has maintained that this does occur. Our cases do not contain a single example of permanent and complete paralysis of muscles, unless possibly in the instances of external ophthalmoplegia. We have not observed fibrillations in the muscles of myasthenics save when there has been an overdosage with prostigmine. Wilson has described changes in the tongue: "A triple shallow longitudinal furrow is frequently found on the tongue, one running along the raphe and one on each side, midway between the former and the lateral edge."

Subjective sensory changes are described occasionally, but are probably incidental. Pain in the region of the eye led to an erroneous diagnosis of aneurysm. In case 44, pain in the eye seemed the only indication for performing drainage of the maxillary sinus. In this case there was also pain in the legs and arms. Numbness and a sensation of "pins and needles" in the arm were described in one patient.

Tendon jerks were found to be normal in the cases reported here. Tiring of the knee-jerk is said to occur in myasthenia gravis, but a brief rest results in its re-appearance (Wilson).

Course. Myasthenia gravis is essentially a chronic disease, characterized by remissions, which usually are partial, and by exacerbations. In this series, among 63 patients, there were 9 deaths during an 11-year period. Since, however the cases were being collected during this period, these figures have no statistical value. The longest duration of the disease in a non-fatal case was 27 years, and it is noteworthy that this patient suffered at first only from weakness of the ocular muscles. The shortest course was $3\frac{1}{2}$ months.

Respiratory infections are often asso-

ciated with exacerbations, and such cases have been observed. Pregnancy frequently has a favorable influence, and remissions commonly occur and persist for several months after delivery (Viets and others). It is of some interest that normal labor appeared to precipitate the disease in case 53. In case 54 an abortion was performed during the first trimester of pregnancy.

In fatal cases, respiratory paralysis is the usual cause of death. The injection of prostigmine is quite often a lifesaving procedure. Grinker mentioned cardiac failure as a cause of death in myasthenia gravis, and in this regard the report of Rottino and his co-workers is of interest.

Clinical tests. The production of fatigue by repeated voluntary efforts has already been mentioned. Closing and opening the eyes may bring on ptosis, and movement of the eyes in various directions may produce limitation of ocular movements. Counting aloud brings out a nasal quality of the voice. The patient may be unable to drink a glass of water.

Apparatus such as the dynamometer may be used to record the strength of the hand-grasp. These tests, when repeated after the injection of prostigmine, point to an increased strength of the muscles.

Electric-response tests. The myasthenic reaction—Jolly's reaction—is not specific for myasthenia gravis since it occurs in other conditions, such as polyneuritis, extreme debility, in some cases of epidemic encephalitis, and in cases of brain tumor (Wilson). Furthermore, absence of the myasthenic reaction is occasionally observed in undoubted cases of myasthenia gravis.

The reaction consists of progressive loss of response to rapid stimuli ("faradic" current), whether constantly or intermittently applied. Usually the apparatus employed has 60 cycles per second (60 C.P.S.). Following such loss of re-

sponse a rest period of several minutes allows the response to reappear and again follow approximately the same course. When a muscle fails to respond to such stimulation, it may respond to voluntary effort, and, conversely, when it has failed to respond to voluntary effort, it may do so to electric stimulation.

Slow stimuli ("galvanic" current) also account for progressive loss of response in the muscles stimulated, but it has been found that complete abolition of response with this type of current is not so readily obtained as with the more rapid type.

Mention has been made of electromyograms.

Tests with drug substances. Prostigmine methylsulfate, when injected subcutaneously in doses of from 0.5 to 1.5 mg., produces pronounced improvement in the muscle power, usually within 5 minutes, but occasionally within 20 or 30 minutes. If more than 0.5 mg. is given, 0.5 mg. atropine should be added. Ptosis is invariably improved or abolished, and other weaknesses are diminished. The muscles attached to the globe are particularly resistant to prostigmine, and increase in the range of ocular movements cannot be anticipated, although sometimes it does occur. As a result of prostigmine administration abdominal cramps, diarrhea, and loss of control of the sphincters may occur in individuals who do not suffer from myasthenia gravis. An injection of atropine is sufficient to allay these symptoms. In myasthenics large amounts of prostigmine may produce cramps and diarrhea unless sufficient amounts of atropine are given.

It is noteworthy that in all, or almost all, cases in which a diagnostic dose of prostigmine has demonstrated fatigability of the muscles, there is a general sense of well-being and increased motor power after its use.

If it is impossible to establish the diag-

nosis on the basis of the history or by the use of prostigmine, quinine may be useful. In the adult one or two doses of 0.6 gm. will almost always increase the symptoms. Such a test occasionally precipitates acute respiratory embarrassment, and in such case an injection of prostigmine gives immediate and dramatic relief.

In case 12 quinidine was given to a patient who exhibited only ocular signs of myasthenia gravis, and since he did not show any evidence of further weaknesses, the diagnosis was questioned. It would seem that since this patient suffered only from severe ocular-muscle involvement, it was impossible to detect an increase in his signs if, indeed, they were increased.

Laboratory tests. These have little or no value either in establishing the diagnosis or in evaluating the progress of myasthenia gravis.

According to Williams and Dyke, creatinuria is a definite symptom of myasthenia gravis. Adams and Power were unable to find any abnormality in blood chemistry. These observers found pronounced creatinuria in 6 of 28 cases, and the extent of the creatinuria did not seem to bear any relationship to the severity of the disease. In almost all their cases the feeding of glycine increased the output of creatine in the urine. Adams, Power, and Boothby also found increased creatinuria after feeding glycine. Nevin found that the phosphorus-holding compounds of muscles in myasthenia gravis were normal, and he concluded that there is no abnormality of muscle metabolism.

TREATMENT

Prostigmine methylsulfate, from 0.5 to 1.5 mg. per hypodermic syringe, is used mainly in diagnosis, but is valuable also in emergencies, such as respiratory failure. The oral administration of prostigmine bromide is now generally accepted as the proper routine treatment. It is

available in 15-mg. tablets and is given in different amounts according to the severity of the case. It seems a good working rule to give it often in such small amounts as afford relief. In mild cases 15 mg. given three times daily may be sufficient, but in severe cases 150 to 180 mg. or more may be given in divided doses every three hours. In such cases it may be found advantageous to combine ephedrine, 0.25 gm., twice or oftener during the day. If considerable amounts of prostigmine are being used atropine is usually necessary to control abdominal cramps and diarrhea. Viets has written on this subject on the basis of a wide experience.

Mention of thymectomy has already been made. X-ray therapy applied to the thymus is said to have influenced some cases favorably.

We have not had experience in the use of synthetic adrenal cortical extract, as described by Moehlig.

DIFFERENTIAL DIAGNOSIS

In the cases recorded here, mention is made of several conditions which were confused with myasthenia gravis. Since, in a majority of cases, the diagnosis of myasthenia gravis demands a correct analysis of ocular signs, it would necessarily follow that conditions regularly associated with ocular signs may be mistaken for myasthenia gravis or vice versa. Ocular signs occurring as the result of abnormal thyroid states may also characterize myasthenia gravis, and the latter and hyperthyroidism may coexist. Abnormalities in associated movements of the lids which have been shown to result from misdirection of regenerated fibers in the third nerve may also be observed in myasthenia gravis when there is no change in the nerves. A mistaken diagnosis of congenital aneurysm was made in case 17. It seems that infrequently in myasthenia gravis the involvement of

muscles results in a picture almost like that seen when there is paresis of the third nerve, but in myasthenia gravis the pupillary responses remain intact. Since describing the ocular signs of intracranial aneurysm (Walsh and King), we have observed a case of aneurysm in which there was evidence of third-nerve involvement but absence of any change in the pupil. Such cases are undoubtedly rare, and consequently it seems sound to state that apparent third-nerve paralysis without pupillary change should always suggest the possibility of myasthenia gravis, whereas third-nerve paralysis associated with internal ophthalmoplegia is often due to aneurysm.

Myasthenia gravis may erroneously be diagnosed in the presence of muscular dystrophy which has involved the facial muscles, and in this regard case 63 is of interest.

An acute episode of respiratory failure as a result of myasthenia gravis may be confused with a similar occurrence in the bulbar type of poliomyelitis or encephalitis, in which instance the diagnosis can be established only by an injection of prostigmine. Such an episode in myasthenia gravis could be confused with acute hypoglycemia.

The occurrence of diplopia as an early symptom of myasthenia gravis suggests that, in differentiating it from disseminated sclerosis, confusion can arise. In some such instances the diagnosis must remain in doubt until further symptoms develop, or other features seen in disseminated sclerosis may serve to establish that diagnosis.

The ocular signs of myasthenia gravis require differentiation from those of external nuclear ophthalmoplegia and from recurrent ophthalmoplegia, which is most frequently caused by aneurysm. In these conditions there is no response to prostigmine.

In the peripheral types of myasthenia gravis confusion might arise with muscular dystrophies and atrophies. In myasthenia gravis there is an absence of wasting which distinguished the conditions mentioned, and, further, there is an absence of fibrillations of the muscle fibers which characterize muscular atrophies, and absence of the reaction of degeneration which is seen in spinal muscular atrophy.

Finally, myasthenia gravis has been described as being associated with the chronic stage of epidemic encephalitis. I have not seen such cases, but it seems probable that cases described as encephalitis with myasthenia gravis represent true myasthenia gravis.

PART II. THE OCULAR SIGNS

Material. This study is based on 63 proved cases of myasthenia gravis studied in the Johns Hopkins Hospital between 1932 and 1943. Approximately 25 percent (15 of 63) of these patients first sought advice from an ophthalmologist.

Most of the examinations were reasonably complete, and included mention of the lids, ocular movements, pupils, and visual acuity. The visual fields were charted in a minority of the cases and accommodation power was accurately measured in relatively few. A majority of these patients were observed by the present writer.

Frequency of ocular involvement. We did not observe a single patient in whom there was no evidence of ocular involvement. In a great majority of them ocular symptoms and signs were early, but in several cases there was a history of weakness elsewhere during prolonged periods before the ocular muscles were affected.

Purely "ocular" myasthenia gravis. In some instances myasthenia gravis seemingly affects only the ocular muscles during lengthy periods, but such localization

does not preclude spread of the weakness, even after many years. Furthermore, in cases of "ocular" myasthenia gravis the injection of prostigmine invariably gives the patient a sense of well-being, even though the affection seems localized in the eye muscles. Cases 6 to 15, inclusive, represent what might be regarded as ocular myasthenia gravis. In one instance there was a history of onset some 13 years before the patient was examined by us. During that time there had been remissions and exacerbations which always affected the ocular muscles. Other writers have observed the affection to be restricted to the eye muscles for prolonged periods, and in this regard Gavey's patient is of particular interest, since he suffered from such an ocular affection for 25 years. One of our patients, after having suffered from recurrent diplopia and ptosis for 16 years, developed a spread of muscle weakness.

It would seem reasonable to test individuals suffering from what appears to be purely ocular myasthenia gravis with quinine. We have tested only one such individual, in whom there was no increase in signs. When the affection is generalized, the symptoms are increased.

Predominance of ocular involvements.

The relative frequency and the early involvement of the ocular muscles do not require statistical confirmation. The predominance of the ocular-muscle participation in the syndrome can well be the basis of much speculation, particularly when the following considerations are taken into account. It has been shown that the extraocular muscles are finer than other voluntary muscles, and that they contain two types of fibers, one of which is thick and the other thin. These muscles contain a large amount of elastic tissue in the perimysium. Further, the complicated structure of the muscles receives an elaborate nervous supply, which is not simply

motor, from the third, fourth, and sixth nerves. There are other fibers which, according to Woollard, originate in the mesencephalic root of the fifth nerve and have a proprioceptive function. Also, as

enched by prostigmine. With these observations in mind, it would seem possible that ultimately the frequency of "ocular" myasthenia gravis may be worked out.

Ptosis. Ptosis of the lids of one or both

Fig. 5 (Walsh). Muscle action potentials during repetitive stimulation of the ulnar nerve in a patient with myasthenia gravis. (A) Initial tetanus after rest. (B) Second tetanus 10 seconds after the first. (C) Same as (B) 30 minutes after use of prostigmine. All nerve stimuli supramaximal. Time, 0.2 seconds. Initial potential, 6.0 millivolts (Harvey and Masland).

mentioned under the head of etiology, acetylcholine has a selective action in producing a slow tonic contraction of the normal extrinsic muscles of the eye (Duke-Elder). For some reason, in many cases paralysis of muscles attached to the eyeball are slightly, if at all, influ-

eyes is almost always present at some time during the course of myasthenia gravis. There is rarely retraction of the lids, but in one instance we have observed retraction which was preceded by ptosis. When our patients were examined bilateral ptosis was present in 34 instances,

and unilateral ptosis, in 20. In two cases it was mentioned as being absent, and in seven cases it was not mentioned. Characteristically, ptosis is most pronounced after the patient has become tired, and consequently it may be absent or minimal in the mornings. In severe cases the lids may be opened widely only once or twice after the patient awakes from sleep. Ptosis on one side may be

When more than one ampule is injected, there should routinely be included 0.5 mg. (1/100 gr.) atropine. If the ptosis has been more pronounced on one side, the lid on that side may be elevated less than its fellow of the opposite side (fig. 7). In many cases ptosis is relieved by prostigmine when the muscular palsies are affected scarcely, if at all.

Edema of the lids. This symptom has

Fig. 6 (Walsh). Before and after injection of prostigmine (case 2).

associated with pronounced weakness of the orbicularis oculi, and with other facial weaknesses, and in such cases the eyelids cannot be opened widely or closed tightly. This combination of weakness both in opening and in closing the eyes was observed frequently in the cases here described, and it has seemed that there is always some weakness of lid-closure when ptosis is present. Ptosis is frequently associated with limitation of extra-ocular movements in one or both eyes. Myasthenia gravis may, of course, occur in an individual with congenital ptosis. Curtis and Sitler described such a case.

It has been our experience that the injection of prostigmine methylsulfate, in amounts of from 1 to 3 c.c. of a 1:2,000 solution (ampules containing 0.5 to 1.5 mg. prostigmine) invariably produces improvement or disappearance of the ptosis and occasionally results in retraction of the upper lid (case 2, fig. 6).

been observed by Klar, who considers local edema and generalized urticaria as prodromal symptoms in myasthenia gravis. We have observed edema of the lids as the earliest involvement in case 5, in which the ptosis remained when the edema disappeared. In case 45 there was a widespread maculopapular rash at the onset of the affection, and recurrence of the rash with exacerbation. The significance of these symptoms is not at all clear.

Retraction of the lids. Retraction of the upper lids is observed infrequently in individuals who suffer from myasthenia gravis. In this series it was unilaterally present in two cases. In both instances retraction was associated with lid-lag. In case 11 retraction appeared and persisted after ptosis had previously chronically been present. Such a transformation from ptosis to retraction has been described by Collier. Buzzard observed bi-

Fig. 7 (Walsh). M. J. F. (case 11). Note the staring appearance of right eye. There was "lid-lag" when the patient looked down. There is drooping of the left upper lid when the eye is abducted and slight elevation of the left lower lid when that eye is abducted. The lowest figure shows the appearance after a diagnostic injection of prostigmine.

lateral retraction of the upper lids as a transitory phenomenon in a patient who suffered from myasthenia gravis. There was retraction, which lasted for only a few

minutes when the patient awakened, and then ptosis appeared and persisted. These observers regarded the retraction as evidence that the plain muscle fibers of the

lids are not involved in the myasthenic process.

The combination of ptosis in one eyelid and retraction of its fellow of the opposite side results in an unusual picture (fig. 7). The fact that retraction developed after there had previously been ptosis points to the abnormality being peripheral in myasthenia gravis.

An explanation for retraction of one or of both lids in myasthenia gravis is not readily available, but the phenomenon does stimulate speculation. It is interesting to compare figure 7 with figure 6. It may be observed that in case 2 the injection of prostigmine was responsible for the retraction of a previously ptosed lid; that is, it produced the same condition that was chronically present in the right eye in case 11. If it is acceptable that acetylcholine is the transmitter substance responsible for the contraction of skeletal muscle, and if it is further acceptable that the threshold of the muscle for this substance may be lowered, it would seem to follow that in case 11 the elevator muscle of the right upper lid had become exquisitely sensitive to acetylcholine. The lid-lag in case 11 and case 48 suggests activity of the plain muscle in the lids.

In unilateral cases, such as case 11, another explanation might be offered. If an extraocular muscle is paretic and the eyes are turned toward the field of action of that muscle, there is a secondary deviation of the sound eye. The retraction of the upper lid of the right eye in case 11 might represent a state of secondary deviation. However, if this were a true explanation of the anomaly, unilateral retraction of the lid would commonly be seen in myasthenia gravis. Further, bilateral retraction does occur.

Actually, retraction of one or both upper lids occurs under a variety of circumstances in which explanation is dif-

ficult. It may be observed in hyperthyroidism, and mention is made further on regarding the possible relationship between ocular signs in hyperthyroidism and in myasthenia gravis. It also is seen in association with lesions of the brain stem and posterior commissure (Collier), and it occasionally occurs as a transitory phenomenon in persons whose health seems excellent. A congenital variety has been described.

Abnormal associated movements of the upper eyelid. In two cases an interesting anomaly was observed in an associated movement of the upper eyelid. In case 11 (fig. 7), previously mentioned in association with retraction of the upper lid of the right eye, there was abnormal lowering of the upper lid of the left eye when that eye was carried into the abducted position. In case 44 (fig. 8), when the eyes were carried into the field of the paretic left external rectus muscle, there was anomalous elevation of the right upper lid.

Both phenomena are precisely similar to what has been described regarding the upper lid in cases of regeneration of the third nerve with misdirection of fibers (Bender; Ford; and Ford; Walsh and King). In cases of misdirection of fibers there is elevation of the upper lid when the affected eye is adducted; that is, when it is moved into the field of the internal rectus muscle, which is also innervated by the third nerve. In the instance of the eye being abducted, the upper lid is abnormally lowered, presumably because the eye is taken out of the field of action of the internal rectus. This is in conformity with Sherrington's law of reciprocal innervation, which is to the effect that contraction of an ocular muscle is associated with simultaneous relaxation of its opponent muscle. However, the upper-lid phenomena observed in cases of myasthenia gravis cannot be due to misdirection of nerve

fibers, since, so far as we are aware, there is no change in the nerves in myasthenia gravis. That the law of reciprocal innervation is still in effect when myasthenia gravis is present can scarcely be doubted, and in myasthenia the muscular involvements are such that abnormal lowering of

bilateral, is frequently present in myasthenics. Wilbrand and Saenger found weakness of the orbicularis oculi in 25 of 45 individuals suffering from myasthenia gravis (Taylor, in Posey and Spiller). In our series, 16 cases showed bilateral facial weakness, and in all of

Fig. 8 (Walsh). Paresis of the left external rectus muscle and ptosis of the left upper lid. Note the abnormal widening of the palpebral fissure on the right when the eyes are directed to the left. The right eyebrow is considerably lower than the left.

the upper lid when the eye is in abduction is an anticipated result. The retraction of the upper lid in case 44 probably is dependent upon changed threshold of the ocular muscles for transmitter substance.

Weakness of the orbicularis oculi and facial muscles. It has previously been stated that facial weakness, almost always

these the orbicularis oculi was weak. As a result of this weakness, there is an inability to close the eyelids tightly. In only two cases was there apparent to the examiner only weakness of both orbicularis muscles. Ptosis in myasthenia gravis is often associated with weakness in closure of the eyelids, which is mani-

fest if looked for. Undoubtedly, in all cases in which there is ptosis there is also some degree of weakness of the orbicularis, a symptom that can be elicited by repeated efforts at tightly closing the

Fig. 9 (Walsh). Exposure keratitis in Negro suffering from myasthenia gravis (case 32).

eyelids. In one instance (case 32, fig. 9) we observed exposure keratitis.

In bilateral or unilateral incomplete facial-nerve paralysis efforts to close the eyelids almost invariably result in the oc-

currence of Bell's phenomenon (upturning of the eyes on efforts to close the eyelids against resistance). This was observed in two cases in which the facial weakness was that of myasthenia gravis. The reaction of degeneration (R.D.) is quite different from the myasthenic reaction.

Limitation of ocular movements. Limitation of movement of the eyes due to weakness of the extraocular muscles varies within wide limits. In mild cases there may be occasional diplopia when examination does not reveal limitation in range of movements of either eye. In such cases there is danger of the condition being considered "functional." The muscle-balance tests vary from time to time.

In other cases characterized by minimal ocular involvement there is diplopia, which appears regularly in association with slight degrees of ptosis. Occasionally there may be limitation of movement, restricted to the field of a single muscle. Minimal involvements of the extraocular muscles may persist for long periods. When cases of this nature are encountered, repeated efforts to move the eyes into various positions usually bring out a manifest limitation in the range of movements in one or more fields.

It has often been stated that inability to move the eyes upward is seen most often, that limitation or loss of convergence is next in frequency, and defect in downward movement is the least common defect in myasthenia gravis. This study neither supports nor refutes this generalization. It does show that limitation of movement of the eyes may be unilateral or bilateral and in any direction, and that sometimes there is a close resemblance to supranuclear paralysis of conjugate movement.

In quite a number of cases in this series there was pronounced limitation of the

extraocular movements, and in such cases there invariably was severe bilateral ptosis. These cases of myasthenic ophthalmoplegia are of particular interest for two reasons: First, the extraocular palsies exhibit a pronounced and characteristic resistance to improvement when prostigmine is used as a diagnostic or therapeutic agent. In our cases the ptosis invariably was lessened or abolished by the administration of a diagnostic injection of prostigmine. The paresis of the extraocular muscles invariably was improved slightly, if at all. Secondly, there is the possibility that in such cases of almost complete external ophthalmoplegia there may be a permanent structural change in the muscles which amounts to persistent and total paralysis.

As regards myasthenia gravis and involvement of ocular muscles of only one eye, the series contains several cases of interest. Such cases have been reported by Moore.

Cases of myasthenia gravis in which there appears to be paralysis of conjugate movements of the eyes are unusual, but we have observed two such cases.

Pupillary changes. It has often been stated that in myasthenia gravis the pupillary response to light may become sluggish (Wilson, Brain, Rea, among others). This has not been our experience. Furthermore, it would seem that there would be a tendency toward pupillary dilatation in individuals with severe myasthenia if the pupillary reaction tended to tire—and there is no such tendency so far as the author is aware.

Changes in accommodation. Rabinovitch and his co-workers demonstrated a rapid reduction in accommodation power by recession of the near point from 7 to 40 cm. in the right eye, and from 12 to 40 cm. in the left eye; according to retinoscopic examination, their patient exhibited a spasm of accommodation when

the test was begun. The cases which have been used in this study cannot be considered as contributing to our knowledge regarding accommodation in myasthenia gravis.

The visual fields and visual acuity. There was no instance among the cases here reported of any change in visual acuity or in the visual fields.

Ocular signs common to thyroid states and myasthenia gravis. The ocular signs associated with thyroid states are generally well known. The same signs may be present in myasthenia gravis. Such signs, as exemplified in the writer's case reports, are: progressive exophthalmos, retraction of the upper lid with delay in down-following movement (lid-lag), difficult or absent convergence, and muscle palsies, which are particularly likely to be pronounced in so-called exophthalmic ophthalmoplegia.

Examination of the muscles in exophthalmic ophthalmoplegia and in some instances in myasthenia gravis may reveal the presence of lymphoid cells in both.

As regards the response of the paretic ocular muscles in exophthalmic ophthalmoplegia to prostigmine, this study is not pertinent. In myasthenia gravis associated with paralysis of the extraocular muscles the injection of prostigmine rarely does more than improve or abolish the ptosis, and in exophthalmic ophthalmoplegia ptosis usually is not present.

SUMMARY OF OCULAR SIGNS

This study has nothing to add to what has already been written regarding the ocular signs of myasthenia gravis.

However, the following observations were made: (1) Ocular symptoms and/or signs were present in all cases. (2) Purely "ocular" myasthenia gravis was observed several times, but in such cases there is always the possibility of spread of the weaknesses. (3) The ocular symptoms

and signs usually appear early in the course of the disease, but occasionally they are a late development. (4) Ptosis is the most constant ocular sign. (5) Edema of the lids is a rare prodromal sign. (6) Retraction of the lids is a rare ocular sign which was observed in one case after a chronic ptosis. (7) The similarity of abnormal associated movements of the lids in myasthenia gravis, and as a result of misdirection of regenerated fibers in the third nerve, was noted. An explanation for these lid phenomena in myasthenia gravis was not attempted. (8) Weakness of the orbicularis oculi may occur in the absence of ptosis or with it. Probably

weakness in closure of the lids is overlooked more often than any other common ocular sign. (9) Limitation of ocular movements occurs unilaterally or bilaterally and in almost all combinations. (10) When pupillary abnormalities are present, it is doubtful if the case is one of myasthenia gravis. (11) Changes in accommodation were observed in only one case. (12) The visual fields and visual acuity are not altered. (13) The similarity of the ocular signs seen in myasthenia gravis and in thyroid states is noteworthy.*

THE STANDARDIZATION OF SO-CALLED SCHIÖTZ TONOMETERS*

PETER C. KRONFELD, M.D.

Chicago 6

The word "so-called" has been added to the title to express the well-known fact that many of the Schiötz tonometers in use in the United States do not meet the physical specifications set up for such tonometers by Schiötz himself, not to mention the more rigid specifications set up by more recent workers in this field. Differences between the standard tonometer which Schiötz used in his calibration work and the tonometers used in the practice of ophthalmology may be the result of inaccurate, careless construction as well as of wear and tear. While a certain amount of the latter was unavoidable (because of the nature of the metals used), differences in construction could have been eliminated if all manufacturers had been induced to turn out only accurate replicas of the original instrument. No official action of that sort was taken, and the manufacture of Schiötz tonometers was taken up by a number of small firms and independent instrument makers who copied an original Schiötz instrument to the best of their ability and understanding. The situation was made worse by the fact that in some respects instruments manufactured and certified under the supervision of Schiötz and his technical assistant A. Tandberg did not comply with their own specifications. Among the 27 original Schiötz tonometers which I have examined and tested there has not been a single one whose plunger assembly (that is plunger plus lowest weight plus hammer and pointer) exerted the specified weight of

5.5 grams. In the majority of these tonometers the plunger assembly weighed between 6 and 6.2 grams; that is, about 11 percent more than specified. Posner and Schoenberg¹ have obtained similar findings. The resulting error amounts to about 3 mm. of intraocular pressure within the range of 20 to 30 mm.

The inaccuracy of the German reproductions of the Schiötz tonometer and its effect upon practical tonometry became very apparent after World War I. The need was felt of methods to determine (1) how much a given instrument deviated in its physical properties from those of a Norwegian standard instrument and (2) what the effect of such deviations was upon the tonometric reading with a representative group of human eyes. To subject a given tonometer to such methods means standardization. Personally I feel that standardization should, if possible, include measures to correct deviations found under (1), so that on a representative group of eyes, the particular instrument will give readings closely approximating those of a standard tonometer. It should be remembered that standardization and calibration are two different things. The latter term implies the conversion of tonometric readings into units of intraocular pressure, whereas the former comprises measures that will assure a uniformity of the tonometric reading with different tonometers.

During the last 20 years the problem of standardization has received a great deal of attention. Much talent, ingenuity, and plain "elbow grease" have been applied to it. The net result is that there still is no simple, generally accepted meth-

* From the Illinois Eye and Ear Infirmary, The University of Illinois. Read before the Chicago Ophthalmological Society on March 20, 1944.

od of standardization (Sachs and MacCracken²). In principle two methods are in use:

1. The physical properties of the tonometer in question are measured with suitable gauges, calipers, and scales and compared with those of a standard tonometer.

2. The performance of the tonometer in question is compared with that of a standard instrument on the eye or eyes of animals, or on a cornealike membrane which is part of an "artificial eye."

It might be well to review briefly the principles of tonometry with an instrument of the Schiötz type. During the application of the instrument two independent weights rest upon the eye. There is the foot plate plus cylinder, frame, and graduated arc which weigh roughly 11 grams and rest upon a fairly large portion of the cornea. The curvature of the footplate is very much less than that of the cornea. The natural effect of the application of the foot-plate assembly is an "applanation" of an area of the cornea the size of which depends upon the intraocular pressure. The lower the intraocular pressure the greater is the flattened-out area of cornea. The change in shape and curvature of the cornea brought about by the foot-plate assembly is called the *deformation* or *distortion*. The second weight is incorporated in the plunger assembly, that is the plunger plus weights, hammer, and pointer. This is the weight that should be 5.5, 7.5 or 10 grams, respectively. To this weight pointer and hammer contribute an amount of about 2.2 grams, varying slightly with the position of the pointer. The plunger assembly indents the central portion of the cornea. This change in shape and cornea is called the *indentation*. It is the depth of that indentation beyond the level of the deformation which the tonometer measures and records 20 times magnified as the so-

called *tonometric* reading or *swing*. In the light of this analysis the essential physical properties of the tonometer would be: (1) size and curvature of the foot plate, since they determine the shape of the deformation; (2) the weight of the foot plate assembly, since it determines the size of the deformed flattened bulbus area; (3) diameter and curvature of the end of the plunger, since they determine the shape of the indentation; (4) the weight of the plunger assembly, since it determines the depth of the indentation; (5) the lever ratio and general construction of the magnifying and recording device.

Now let us turn to the ocular factors which determine the tonometric reading. Obviously, the main factor opposing indentation and deformation is the intraocular pressure. The experimental work of Schiötz and Priestley Smith revealed considerable and consistent variations of the tonometric reading on eyes whose intraocular pressure had been brought to exactly the same level. Logically, Schiötz thought that differences in ocular size and in thickness and elasticity of the eyeball wall account for these variations. Friedenwald's brilliant mathematical analysis of tonometry³ has taught us to distinguish clearly between two factors that determine the impressibility of the eye, which is what the tonometer measures. With an ingenious method based upon two successive tonometries with widely divergent weights Friedenwald showed that the tonometric reading could be broken down into its two components, the intraocular pressure and the ocular rigidity. Unfortunately, the tonometers that have been available during the last 10 years are not accurate enough to permit reproducible rigidity determinations except under very favorable conditions. In my own hands, Friedenwald's method has convinced me of the existence of consistent differences

in ocular rigidity in different eyes. I do not believe that I know the limits of physiologic variations of ocular rigidity, although they must be about as great as those suggested by Schiötz's findings in his calibration work. It is to be hoped that postwar refinements of the Schiötz tonometer will permit accurate rigidity determinations on a large scale, which, I am confident, will confirm the soundness of Friedenwald's concept. Until then I believe we shall have to assume, in the practice of ophthalmology, that the eyes whose intraocular pressure we wish to determine by tonometry possess *average* ocular rigidity, and convert tonometric readings into millimeters of intraocular pressure by using Schiötz's nomogram of 1924⁴ with the minor corrections suggested by Friedenwald in 1937.

The concept of ocular rigidity has a very definite bearing upon the standardization of tonometers if the latter is done on single artificial, animal, or human eyes. If this eye possesses average ocular rigidity, it is probable that two tonometers which check well on this eye (or device) will also check well under ordinary clinical conditions. If the eye or device used for standardization does not possess average rigidity it is not certain at all that a match between two tonometers under laboratory conditions will remain a match in clinical practice. Eyes with average rigidity usually give identical or parallel calibration curves. Eyes with low or high rigidity often give calibration curves that are not parallel to those of eyes with average rigidity. For that reason I believe it is necessary that standardizations done on animal or human eyes are made either on eyes proved to possess average rigidity or on large enough groups of eyes to make it probable that all variations of ocular rigidity are duly represented.

Standardization of tonometers by comparing the performance of unknown

with that of a standard instrument on a representative specimen or group of animal or human eyes is cumbersome and difficult. It would be very time-consuming to carry out a large number of such standardizations.

The Committee on Standardization of Tonometers of the American Academy of Ophthalmology and Otolaryngology has adopted the other method of standardization; that is, the measurement of all important physical properties of the instrument. The details of the method have been worked out by Posner.⁵ The main steps of the procedure concern: (1) size and curvature of the foot plate; (2) diameter and curvature of the end of the plunger.

If these measurements prove to be within the limits of tolerance approved by the Committee, the examiner proceeds to weigh: (3) the foot plate assembly and (4) the plunger assembly.

In these measurements determinations of the friction between cylinder and handle and the friction affecting upward movement of the plunger are included. The latter consists of the friction between plunger and cylinder, between plunger tip and the undersurface of the hammer, and at the fulcrum.

Finally, the magnifying and recording device is checked; a micrometer gauge providing indentations of varying depth is used for this purpose.

The deviations from the standard encountered most commonly are faulty weights of either the foot plate or the plunger assembly or inaccuracies of the magnifying and recording device, the lever ratio being greater or smaller than 1:20 or being discontinuous.¹ The effect of all these deviations upon the tonometric reading can be figured out mathematically following principally Friedenwald's theory of tonometry, and the respective correction factors can be determined.

Thus it is possible, if the curvature and size of the foot plate and plunger end are within tolerable limits, to correct the existing deviations by providing a new calibration curve for the particular instrument. Such calibration curves have, in some instances, been very irregular and discontinuous. The computation of these curves has occasionally been so complicated that I have had doubts as to the reliability of the final result.

For that reason I started about 18 months ago to subject nine of these "corrected" tonometers to a rigid checking on a representative group of human eyes. Patients from my private practice as well as from the Illinois Eye and Ear Infirmary volunteered for this purpose after they were told that I would like to check their intraocular pressure with two dif-

ferent instruments. Patients with known or rather consistent ocular rigidity were selected for this purpose. The range of intraocular pressures covered was from 15 to 45 mm. of mercury. Each tonometer was compared with a standard on at least 20 different human eyes. While this again was a time-consuming process it was very gratifying to see that tonometers corrected by the foregoing method showed no significant differences in the tonometric measurements in more than 1 out of 10 checks of human eyes. Thus I proved at least to my own satisfaction that our method of correcting tonometers made them perform in close agreement with the standard. The method of standardizing tonometers by measuring the physical properties is therefore practically sound.

THE LENS IN ACCOMMODATION*

JOHN G. SINCLAIR, PH.D.
Galveston, Texas

The mechanism of accommodation has intrigued students of the eye, and a number of theories of its action have been proposed. Acceptable theories have in common the requirement of an elastic lens and an equatorial ligament pulling almost radially with sufficient force to change the form of the lens and give the eye a change of refracting power from 70.6 to 56.6 diopters. Fincham's observations placed the compressive force in the capsule and noted that the lens substance seemed to bulge through an opening as though it were pressing outward on the capsule at all points.

One difficulty with the theory of accommodation by relaxation has been the force required to change the lens form by elastic compression. Adler points out that the theoretical tension on the choroid at rest would destroy it. The ciliary muscle is small, particularly the long fibers which tense the choroid in relaxing the lens ligament. The lens is made of a very firm center whose rods are axially directed and not easily deformed even by finger pressure. And yet it is obvious to the touch that the axial diameter as a whole can be easily reduced. The interior of the lens, therefore, was investigated to find any feature that would permit a small force to accomplish large changes in form.

The lens develops from an ectodermal vesicle whose medial wall grows into long parallel lens rods, whereas the lateral wall remains a cellular lens membrane. Additions of cells to the nucleus at its margins are made from this membrane, so that from the beginning the lens form grows flatter and its focal length increases. Long before birth the lenticular portion of the

central retinal artery is obliterated, and the rods at or near the axis receive less nutriment and oxygen. As they fail to elongate, peripheral rods curve over them both medially and laterally from the equator toward the axis. Up to the time of birth this spheroidal lens is a continuum from the protoplasmic outer rods, with a refractive index of 1.33 to the non-living dense protein mass of the center, where, in the adult, rod structure is not easily demonstrated. The refractive index of this center rises to 1.46. After birth, as the lens grows and at the same time functions increasingly in accommodation, stresses are set up tangential to the surface, and the rods become aligned in sheets. Between the sheets is albuminous liquid. One stress zone in particular contains more liquid than the rest and separates the nucleus from the surrounding cortex. The cortical lamination is equivalent to the menisci pictured by Cowan with diagrammatic simplicity.

The mature crystalline lens in tension and in relaxation is pictured in figure 1. It is seen that tension at the equator, besides slightly stretching the lens, moves liquid along the stress zone to the equator whereas in relaxation liquid moves back to the axis on both sides of the nucleus. The nucleus is held in position by strands that cross the liquid-filled zone, but the whole nucleus is moved forward. The force in this axial expansion is furnished partly through cortical elasticity and partly through hydrostatic pressure probably based on a small differential in osmotic pressure of lenticular fluid over surrounding fluids. The hydrostatic component operates uniformly in all directions, but its effectiveness on any wall varies directly with the radius of curvature of that wall

* From the Department of Anatomy, University of Texas.

and the thickness of the wall. The curved prismatic cortical lens rods in turgor tend to become straight and in doing so supply the necessary elastic component. These

literated and the whole lens becomes, like the nucleus, an unyielding and highly refractive mass. Beef eyes are generally from young animals. The lens is double

Fig. 1 (Sinclair). The mature crystalline lens in tension and in relaxation.

forces, taken together with the fact that the central or pupillary zone of the cortex is thin, permit the change in radius of curvature characteristic of accommodation in this region. This change does not extend to the whole lateral lens face.

The lenticular structure here pictured is found in the human eye after birth. In old age the liquid space is reduced or ob-

the diameter of the human lens, and the structure of the liquid stress zone is easily demonstrated.

The theory of lens elasticity presented here does not call for modification of accepted theories of accommodation but it does make more plausible the effectiveness of the force of tension in the lens ligament.

EXTRACTION OF SENILE CATARACT*

A STATISTICAL COMPARISON OF VARIOUS TECHNIQUES AND THE IMPORTANCE OF PREOPERATIVE SURVEY

WILLIAM F. HUGHES, JR., M.D., AND W. C. OWENS, M.D.
Baltimore 5

When the Wilmer Institute was opened, in 1925, the technique used for the extraction of senile cataract was a combined extracapsular extraction without conjunctival flap or sutures. This original technique has been modified gradually but radically during the past 19 years by the following successive changes: the use of a conjunctival or "pocket" flap closed with sutures; intracapsular extraction by the tumbling method with forceps; the use of one or two corneoscleral sutures; and, finally, the preservation of a round pupil. The material for this study consists of all the operations for uncomplicated senile cataract either by the resident house staff or the full-time staff of the Institute between 1925 and October, 1943, a total of 2,086 extractions. It is the object of this paper (1) to compare the results obtained by the different methods used during this period, and (2) to determine the factors which obviate complications and produce the best end results. In later papers, various details and corollaries uncovered in this survey will be discussed. In this study, no factor will be considered to have any statistical significance unless the probability of error is less than 1 in 20.

* From the Wilmer Ophthalmological Institute of The Johns Hopkins University and Hospital, Baltimore.

Most of this paper was presented at the Forty-ninth Annual Session of the American Academy of Ophthalmology and Otolaryngology, October 12, 1944, Chicago, Illinois. Minor changes have been made as the result of the discussion it provoked.

RESULTS OF VARIOUS TECHNIQUES

When the gradually shifting technique is viewed in retrospect, five distinct methods of extraction become apparent; namely, (A) capsulotomy followed by extracapsular extraction, with a full iridectomy, and without the use of conjunctival flap or sutures; (B) combined extracapsular extraction using a conjunctival flap closed with sutures; (C) combined intracapsular extraction with conjunctival sutures; (D) combined intracapsular extraction with one or two McLean-type silk corneoscleral sutures;¹ and (E) round-pupil intracapsular extractions, usually with two corneoscleral sutures and one peripheral iridotomy. These five groups are of unselected cases, but do not include 436 operations with other combinations of technique; for example, keratome incision followed by capsulotomy and lavage, extracapsular extraction with corneoscleral suture or round pupil, or unsuccessful intracapsular attempts with rupture of the capsule.

The incidence of complications which followed each of the five techniques is given in table 1a. Loss of vitreous occurred most frequently in combined intracapsular extractions, and least often in round-pupil intracapsular extractions. Incomplete closure of the corneal wound at the end of the seventh postoperative day and prolapse of the iris were greatly reduced by the use of one and especially of two corneoscleral sutures. Anterior-chamber hemorrhages occurred most frequently after combined intracapsular

extractions with conjunctival sutures and least frequently after round-pupil intracapsular extractions with two corneoscleral sutures. The incidence of post-operative iridocyclitis decreased markedly with total extraction of the lens. Sec-

Table 1b. Over one third of the extracapsular extractions later had to be followed by at least one dissection to obtain satisfactory vision. In some cases, it was also necessary to reopen the eye with a keratome to perform a capsulectomy or

* Pupillary space occluded by organized material or iris drawn up by anterior synechiae.

** Excluding those without adequate refraction or with extraneous causes of poor vision; for example, senile macular degeneration.

ondary glaucoma became less frequent following intracapsular extractions with corneoscleral sutures. Detachment of the retina was somewhat higher in the early intracapsular extractions with conjunctival sutures.

lavage of cortical remains. In spite of these measures to clear the pupillary space, 16 percent of those having had extracapsular extractions obtained a final vision of less than 20/30 solely because of residual capsular remains or the de-

velopment of Elschnig bodies. Many of these patients refused to have secondary operations performed. In a few instances after intracapsular extractions, it was necessary to perform a secondary operation to open a pupil occluded by organized exudate or drawn up by anterior synechiae. The percentage of eyes having a final astigmatism of 5 diopters or more became progressively less with the use of sutures to close the corneal wound more securely.

Tabulation of the final visual results includes only those patients who had an adequate refraction and had no causes of poor vision independent of the cataract extraction; for example, senile macular degeneration or other pathologic condition. In addition, those patients with a final vision of less than 20/30 because of residual capsular remains were excluded unless an attempt had been made to open the pupillary space by a discission or capsulotomy. The average postoperative follow-up of groups A to E varied, respectively, from 23 months to 6 months, the average for all groups being 14 months. Table 1b shows that the percentage of patients who obtained good vision progressively rose with each change in technique, and, with the exception of group C, the incidence of poor visual results diminished. The gradual improvement in final visual results of each successive method was also manifest in the tabulation of all cases, including those cases excluded from table 1b ("Visual results").

In summary, with each change in technique during the past 19 years, the incidence of postoperative complications has become lower and the final visual results have become better except for the early technique of combined intracapsular extraction with conjunctival sutures used between 1930 and 1937, which was associated with a higher incidence of certain

complications such as loss of vitreous, prolapse of iris, anterior-chamber hemorrhage, and detachment of the retina. The question therefore arises; what are the individual factors in operative technique that have a significant influence on postoperative complications and the final result?

FACTORS IN OPERATIVE TECHNIQUE INFLUENCING POSTOPERATIVE COURSE

1. Residual lens cortex and capsule after nontotal or extracapsular extraction. In this study, a patient was considered to have postoperative iridocyclitis if the eye remained congested externally and the aqueous ray persisted for

TABLE 2
INFLUENCE OF RESIDUAL CAPSULE AND CORTEX ON

over three weeks after operation, if non-specific protein-fever therapy was instituted, or if signs of iridocyclitis developed later (for example, inflammatory changes in the iris, positive aqueous ray, and K.P. deposits on the posterior surface of the cornea). Iridocyclitis was found to be more common after extracapsular than after intracapsular extractions (table 2). Almost one third of the patients with retained lens cortex developed postoperative iridocyclitis. In respect to this complication: Is an unsuccessful attempt at intracapsular extraction (that is, an unintentional rupture of the capsule during delivery) less desirable than an intentional extracapsular extraction with capsulotomy? Analysis of

the figures shows that the incidence of retained cortex and postoperative iridocyclitis was essentially the same in both groups (table 3). Also, accidental rupture of the capsule was not accompanied by any increase in the frequency of vitreous loss compared to successful intracapsular extractions.

Attempted intracapsular extractions have been considered unsuccessful if the capsule ruptured either in the eye or when emerging through the wound. Prior to 1939, 37 percent of capsules were ruptured during delivery. Between 1939 and 1943, 19 percent of capsules were ruptured. The tumbling method with the Kalt forceps was used in the early years and later the Arruga or Castroviejo forceps was substituted. Occasionally the Barraquer suction cup was used for hypermature lenses. The incidence of broken capsules was highest for mature and

Intentional extracapsular (with capsulotomy)	668	16.6	13.0

hypermature lenses, and in patients under 50 or over 80 years of age. Assistant residents were as successful in extracting the lenses in capsule as were operators of more experience. The junior men, however, operated chiefly on eyes in selected cases.

2. *Loss of vitreous.* Loss of vitreous has been classified into three groups: "presentation" of vitreous refers to a re-formed anterior chamber following extraction of the lens without external loss

of vitreous; moderate loss refers to a visible loss of formed or semiformed vitreous; and severe loss indicates the loss of a large amount of formed vitreous usually with softening of the globe. Loss of vitreous predisposed to the develop-

ment of persistent vitreous opacities and simple detachment of the retina (table 4). In addition, loss of vitreous increased the frequency of iridocyclitis after intracapsular extractions, in which group of cases the factors of capsular or cortical remains were excluded (table 4a). The persistent vitreous opacities subsequent to vitreous loss were found to originate from iridocyclitis and vitreous hemorrhage. Over one half of the round-pupil extractions complicated by presentation or loss of vitreous resulted in irregularity of the pupil, often with anterior peripheral synechiae. Uncomplicated round-pupil extractions showed some irregularity of the pupil in 10 percent of the cases.

Relative importance of capsular or cortical remains and vitreous loss with re-

* Excluding those without adequate postoperative refraction or with extraneous causes of poor vision; for example, senile macular degeneration.

spect to the final visual result. The previous figures have shown the undesirable effects of either retained lens material or vitreous loss. If the capsule ruptures inadvertently during an attempted intracapsular extraction, the objectionable effects of residual capsule or cortex must be balanced against the danger of vitreous loss should the attempt be made to remove the residual lens material (table 5). A comparison of the visual results shows that severe vitreous loss and cortical remains are equally deleterious. However, while simple presentation of the vitreous is slightly more detrimental than leaving capsular remains, it is not nearly so seri-

ous as leaving lens cortex in the eye. From this, it would appear justifiable to attempt the removal of lens cortex in all cases even at the possible expense of vitreous loss. On the other hand, the removal of purely capsular material is advisable only if such an attempt is not accompanied by undue hazard of breaking the hyaloid membrane.

3. *Sutures.* Analysis of the data on the basis of sutures alone confirms the previous impression that tight closure of the corneal wound decreases gaping of the wound, prolapse of the iris, and final astigmatism (table 6). In extractions complicated by loss of vitreous, corneo-

TABLE 6a

EFFECT OF CORNEO-SCLERAL SUTURES ON REDUCING SOME COMPLICATIONS OF VITREOUS LOSS

Loss of vitreous	Corneoscleral Sutures	No. of Cases	Incomplete Closure of Wound (7 days) percent	No. of Cases	Astigmatism 5D or More percent
None	None	838	2.3	559	9.8
	Present	861	0.9	602	1.0
Presentation or loss	None	170	14.7	102	27.0
	Present	169	3.5	106	1.9

scleral sutures even more significantly reduced the likelihood of incomplete closure of the corneal wound and a high degree of astigmatism (table 6a). The use of two corneoscleral sutures (table 6) has reduced the incidence of anterior-chamber hemorrhages. The relatively low incidence of anterior-chamber hemorrhages in those cases in which no sutures were used might be accounted for by the shallow corneal sections in vogue at that time.

The use of sutures has been associated with an increase of purulent endophthalmitis, but, as Guyton and Woods have indicated,² this complication can be eliminated by the use of prophylactic sulfadiazine systemically for the first few days after operation (table 6b). The local use of chemotherapeutic agents is not so efficacious. When 5-percent sulfathiazole ointment was used locally in the eye immediately after the operation and usually at each dressing thereafter, two patients of 116 so treated developed purulent ophthalmitis, although stitch abscesses were not encountered. Additional measures that have effectively prevented this complication include an iodine-alcohol clean-up of the skin instead of merthiolate, metaphen, or zephiran, and careful draping in order to cover completely the nose, brow, and most of the skin.

Difficulty was encountered occasionally

in the removal of corneoscleral sutures. The anterior chamber was lost either during the removal of sutures or more frequently was found collapsed the following day in 3.7 percent of 1,030 cases. Serious gaping of the wound rarely ensued, and the anterior chamber ordinarily re-formed within 48-hours. Small anterior-chamber hemorrhages occurred at the time of removal of sutures in 3.6

TABLE 6b

RELATION OF SUTURES AND PROPHYLACTIC SULFADIAZINE TO POSTOPERATIVE PURULENT ENDOPHTHALMITIS

percent of the 1,030 cases. If the suture is deeply placed or if the patient is uncoöperative, removal of sutures can be postponed beyond the tenth postoperative day, and removal will be easier one or two weeks after discharge from the hospital.

4. *Iridectomy.* In the entire series round-pupil extractions have been compli-

TABLE 7
RELATION OF TYPE OF IRIDECTOMY TO LOSS
OF VITREOUS

Iridectomy	No. of Cases	Loss of Vitreous percent
Round pupil	444	2.7
Complete iridectomy	1635	10.6

cated by loss of vitreous less often than when extractions were preceded by a full iridectomy (table 7). It was not the usual procedure to perform an iridectomy following the loss of vitreous during a round-pupil extraction. However, when there was an accidental rupture of the capsule, a full iridectomy was often performed on the previously round pupil to facilitate the removal of capsular and cortical remains.

It has been suggested that the attempt to remove the cataractous lens through a round pupil increases the danger of rupture of the capsule. This is true in the extraction of hypermature lenses, especially when the pupils are rigid and dilate poorly with mydriatics. However, this factor was not important in the usual case of our series. The incidence of

TABLE 8
POSSIBLE FACTORS IN THE PRODUCTION OF

	None	1615	2.9

broken capsules became lower during the last five years when round-pupil intracapsular extractions were attempted in practically every case.

Postoperative anterior-chamber hemorrhages have only a suggestive relationship to the degree of iris trauma at operation.

5. *Factors in the production of secondary glaucoma.* The development of postoperative iridocyclitis, either from residual lens cortex or from loss of vitreous, predisposed to the development of secondary glaucoma (table 8). Other factors that have a suggestive but not statistically significant relation to secondary glaucoma in this series are: nonre-formation of the anterior chamber for at least seven days after operation, capsular and cortical remains without associated iridocyclitis, and presentation or loss of vitreous without iridocyclitis.

INFLUENCE OF GENERAL MEDICAL CONDITIONS ON POSTOPERATIVE COMPLICATIONS

-1. *Foci of infection.* Many of the patients, particularly in the earlier days of the Wilmer Institute, underwent a thorough search for foci of systemic infection prior to operation for cataract. This included a general physical examination by the interne, routine consultation with the nose and throat department (usually including X-ray studies of the sinuses), dental consultation with X rays, consultations with the gynecologic or urologic departments if indicated, blood Wassermann test, urine examination, and often tuberculin-sensitivity tests and X ray of the chest. An analysis of the incidence of postoperative iridocyclitis in relation to preoperative foci of infection revealed a curious finding in the group of patients subjected to extracapsular extraction (table 9). In this group, the patients whose foci of infection (in teeth

or sinuses) were either untreated or inadequately treated showed essentially the same incidence of postoperative iridocyclitis as those with no demonstrable focus of infection. However, the patients whose foci of infection were adequately treated prior to the extracapsular extraction developed postoperative iridocyclitis much less frequently than either the untreated and inadequately treated group or the group with no demonstrable focus of infection. An explanation of this finding is not readily apparent and will be the subject of a future report.

2. *Diabetes.* Only those diabetics who had had diabetes for nine years or more, or required 30 units or more of insulin showed any increase in postoperative complications (table 10). These groups were more prone to develop severe anterior-chamber hemorrhages, defined in this study as either a single hemorrhage completely filling the anterior chamber or smaller recurrent hemorrhages. No significant correlation was obtained between the height of the pre- or postoperative blood sugar, insulin shock, or diabetic acidosis, and any postoperative complication.

3. *Systemic hypertension.* No relationship was obtained between the height of either systolic or diastolic blood pressure and any postoperative complication. Two out of the three patients who developed expulsive choroidal hemorrhages and normal blood pressure, but all were over 70 years of age.

4. *Syphilis.* In this study 105 patients had late and usually latent syphilis. They showed no tendency toward increased postoperative complications. No difference was found between treated and untreated syphilitics.

DISCUSSION

Iridocyclitis. The relative importance of the etiologic factors in postoperative

iridocyclitis is somewhat uncertain. A survey of the literature reveals that iridocyclitis follows extracapsular more frequently than it does intracapsular extractions,³ and we have found that the presence of retained lens cortex widens this difference. The most credible reasons why lens capsule and cortex should predispose to the development of postoperative iridocyclitis are (1) that bacteria are introduced into the residual lens material at the time of operation and therein find a good culture medium for growth, (2) that the individual becomes sensitized to his own lens protein and may develop varying degrees of endophthalmitis phacoanaphylactica, and (3) that lens material has intrinsic toxicity.⁴ In regard

TABLE 10

RELATION OF SEVERITY OF DIABETES TO SEVERE
POSTOPERATIVE ANTERIOR-CHAMBER

to the possible factor of infection, we found that the incidence of purulent endophthalmitis was no higher in extracapsular than in intracapsular extractions, and was lowest in eyes with retained cortex. If infection were usually present in the cortical remains of eyes with iridocyclitis, it would be surprising

tion possess this hypersensitivity to lens protein. A compilation of the data from the literature⁶ shows that the cutaneous test for lens protein becomes positive in the large majority of cases with postoperative iridocyclitis (table 11). It may be that low-grade infection or a toxin facilitates such a sensitization to lens pro-

that purulent endophthalmitis did not develop more frequently. Also we did not find that the prophylactic use of sulfadiazine had a significant effect on the prevention of iridocyclitis, although it is likely that sulfadiazine does not penetrate well into lens cortex. Infection also appears unlikely in those cases which do not develop iridocyclitis until several weeks after the operation. Reports in the literature indicate that such cases of late iridocyclitis often show evidence of cutaneous sensitivity to lens protein, and frequently respond well to lens-protein desensitization. A few of the reported cases with evidence of lens sensitivity have come to enucleation, and have shown the histologic picture of endophthalmitis phaco-anaphylactica.⁵ The question arises whether most of the cases with iridocyclitis following extracapsular extrac-

tein, as Burky has shown experimentally with staphylococcus toxin in rabbits.⁷ This may be the role of foci of infection in the sinuses⁸ or teeth.

SUMMARY AND CONCLUSIONS

The gradual but radical changes in the technique of extraction of uncomplicated senile cataract during the past 19 years at the Wilmer Institute have brought about a steady improvement in final results. Statistical analysis of 2,086 extractions has shown that: (1) the amount of lens capsule and cortex remaining after an extracapsular extraction is directly related to the development of postoperative iridocyclitis, which, in turn, is the main factor in the production of secondary glaucoma; (2) loss of vitreous predisposes to postoperative simple detachment of the retina, persistent vitreous

opacities, and iridocyclitis; (3) corneo-scleral sutures reduce the incidence of incomplete closure of the wound, prolapse of iris, the amount of final astigmatism, and, with two sutures, anterior-chamber hemorrhages; (4) preservation of the round pupil reduces the likelihood of vitreous loss; (5) diabetes of long standing or requiring 30 units of insulin

or more per day predisposes to the development of severe anterior-chamber hemorrhages, but there is no correlation between the height of the blood-sugar and postoperative complications; (6) syphilis, either treated or untreated, and systemic hypertension have no significant influence on the occurrence of postoperative complications.

REPAIR FOLLOWING TUCKING OPERATIONS ON THE EXTRAOCULAR MUSCLES*

K. S. CHOUKÉ, M.D.

Philadelphia

Since the early part of nineteenth century many articles have appeared in the literature concerning operations on the extraocular muscles for strabismus. But, so far as can be ascertained, only two papers have been published on the study of repair following such operations. The first systematic attempt to study this problem was apparently made by Carroll and Blake.¹ Since then Gifford² has observed the position of extraocular muscles after operations for strabismus.

In the study of repair following operations on the extraocular muscles Carroll and Blake used adult rabbits as the experimental animals. For anesthesia they used sodium amytal or pentobarbital sodium intraperitoneally. They used ingenious methods to hold the animal in a suitable position from which it could not move. The animals were killed 2 to 40 days after the operation by electrocution or ether. The following operations were performed on the rabbits' muscles: simple tenotomy, attachment of the muscles to the sclera by sutures, tucking, and resection.

Chouké and Whitehead³ have shown that healing of skeletal muscle of dogs and rats occurs by fibrous connective-tissue growth from the epi-, peri-, and endomysium, and not through regeneration of muscle cells. They also found that the union of muscle to muscle is complete 8 to 11 days after suture.

The experiments here reported were performed on dogs to see whether the repair following operations on extraocular muscles was similar to or different from the results obtained in the case of rabbits by Carroll and Blake. Another object of these experiments was to compare the repair of extraocular muscles with the repair of skeletal muscle in general, since Irvine⁴ has shown that many peculiarities distinguish the ocular from other striated muscles, both in man and in lower animals. Embryologically, in man, there is a possibility of splanchnic origin for the ocular muscles, according to Irvine. Histologically, ocular muscles differ from skeletal muscle in having unusually fine fibers, excessive amounts of elastic tissue, unusual fibers with encircling fibrillae, fibers rich in sarcoplasm, and others with interlacing fibrillae. This picture is somewhat similar to that seen in degenerating muscle in myxedema and various myopathies.

From an anatomic point of view the extrinsic ocular neuro-muscular structure of man is differentiated earlier in the phylogenetic history than the striated musculature elsewhere in the body. A good historical account of muscle tucking is given by Burch and Grant.^{5, 6} Therefore it will not be repeated here.

The results of simple tenotomy, attachment of the muscles to the sclera by sutures, and resection obtained by Carroll and Blake have been confirmed by Gifford. Only two tenotomies were performed on dogs by the present writer. One of these was accidental, for the animal was physically so weak that while the tucking operation was being completed,

* From the Department of Anatomy, Graduate School of Medicine, University of Pennsylvania. Aided by Research Grant No. 503 of the Graduate Board of Education and Research, University of Pennsylvania.

the muscle broke in two almost at its center; it should probably therefore be called a myotomy. The other was intentional and was performed practically in the same manner as simple tenotomy is done for human cases of strabismus. The results of both these operations were for all practical purposes identical with those of Carroll and Blake on the rabbits and those of Gifford on the human eye. In other words, the muscle was found attached to the sclera behind the original insertion in the case of the intentional tenotomy. This animal was killed 28 days after the operation. But in the case of the accidental myotomy the attachment of the proximal end of the muscle could not be definitely established. As stated, the physical condition of this animal was very poor; this may possibly account for no definitely visible gross attachment of the muscle to the sclera. Even though the animal was kept alive for 120 days after the operation, its general physical condition did not show any improvement. Since the results of the operations on these two dogs agreed with those of Carroll and Blake and of Gifford, no further simple tenotomies were performed.

Extraocular muscles were subjected to 38 tucking operations in a series of 20 adult dogs. The experimental animals, as has been mentioned, were all adult dogs. They varied in weight from 7 to 19 kilograms. The animals were killed from 1 to 155 days after the operation by chloroform or ether, excepting one which was bled to death under sodium amytal anesthesia, since its blood was needed for an experiment connected with a war problem. Sodium amytal, 15 mg. per cubic centimeter per kilogram of body weight, was injected intraperitoneally. In a few cases toward the end of the operation a few whiffs of ether were given to keep the animal quiet. In six animals sodium

amytal, 10 mg. per cubic centimeter per kilogram of body weight, was injected intravenously; the results of this method of anesthesia were at least as satisfactory, if not more so, as the intraperitoneal method. The animal was ready for operation in less than 10 minutes after the intravenous injection of sodium amytal, thus proving the latter to be a time-saving procedure. There was only one death in this series that could be attributed directly to an overdose of anesthetic. Two other animals died within 24 hours after the operation; no definite cause of death, however, could be established.

Thirty-eight tucking operations were performed involving either the lateral rectus or the superior rectus muscle. The instrument employed was in some cases Todd's tucker; in others Harrison's or Speas's tucker was used. In a few cases a tuck was placed with a Roberts tucker in the muscle at a distance of 3 to 8 mm. from its insertion, two single silk sutures being used.

RESULTS

Gross. All wounds appeared to be completely healed within 12 days after the operation. Black-silk sutures could be seen easily, thus marking the site of the tuck. The tuck in all cases was covered over by connective tissue. The union appeared to be as firm as in the normal attachment of extraocular muscles to the sclera. In other words, the muscle with a tuck could stand as much pull on it as a normal undisturbed extraocular muscle. In several animals the muscles were seen to be attached to the sclera at or near the point of the tuck. In four cases the two ends of the muscle on either side of the tuck responded to electrical stimulation. A definite twitching of the muscle could be seen after the application of a double fine electrode to either end of the muscle.

Microscopic. Twenty-four to 48 hours after the operation a definite foreign-body reaction had started near the site of the suture. About the fourth postoperative day some of the muscle fibers in the tuck were seen to be disintegrating. Many young fibroblasts, some polymorphonuclear

By the twelfth postoperative day there was a larger amount of fibrous connective tissue replacing the muscle fibers. Foreign-body reaction and granulation tissue were still present. Union of the muscle to the sclera was visible in the region of the tuck in addition to the union between

Fig. 1 (Chouké). Results of tucking on the nineteenth day. The loop of the muscle is shown in this figure in addition to the attachment of the muscle to the sclera (see arrows). H and E stain; $\times 50$.

clear cells, a few small round cells, and a very small amount of fibrin were noted. Probably these conditions were caused by the trauma to the muscle.

On the seventh postoperative day there was seen a dense cellular reaction consisting mainly of small and large mononuclear cells. Many fibroblasts and round cells were also seen in addition to some granulation tissue among the muscle fibers.

the two parts of the muscle to each other. The appearance of the sections on the sixteenth postoperative day was practically the same as that for the twelfth postoperative day.

On the nineteenth postoperative day there was some foreign-body reaction around the silk sutures. In the photomicrograph of a section taken on the nineteenth postoperative day (fig. 1) a loop of the muscle and its attachment to

the sclera can be seen, with slight cellular reaction. Necrotic fibers of the muscle mentioned under the fourth postoperative day are not seen at this stage; apparently they have been absorbed.

On the twenty-eighth postoperative day

cle on either side of the tuck is connected by fibrous connective-tissue scar (fig. 3). Two silk sutures are still present. Under the suture on the left side of the figure attachment of the muscle to the sclera can be seen. Adjacent to the right suture

Fig. 2 (Chouké). Results of tucking on the thirtieth day. Complete loop of the lateral rectus muscle is seen. The lower part of the figure shows the attachment of the muscle to the sclera. H and E stain; $\times 50$.

some muscle fibers have been replaced by scar tissue. Foreign-body reaction is still present around the silk sutures.

On the thirtieth postoperative day a complete loop of the muscle can be seen. Its attachment to the sclera is also visible. There is a noticeably small amount of scar tissue in this section (fig. 2), except at the junction of the muscle with the sclera.

On the thirty-fifth postoperative day the tuck is seen in the center and the mus-

some foreign-body reaction is still present.

During the period between the 35th and 155th postoperative days there is hardly any noticeable difference in the gross picture or in the microscopic appearance of the tissues.

The muscle attachment was accomplished by organization of fibrin and by granulation tissue. Carroll and Blake⁷ also express the same opinion in the following words: "In tucking and resection, the

end result depends upon a bridge of strong connective tissue uniting the loops of the tuck, or the severed parts of the muscle. Occasionally the muscle becomes attached at some distance from the desired point." These observations seem to agree with the statement of Gifford: "It would appear from these findings that necrosis of muscle fibers would actually shorten the muscle more than the calculated amount while the amount of relaxa-

by ophthalmic surgeons in different parts of this country.

SUMMARY

After a tucking operation the two adjacent sides of the loop of muscle join together by means of fibrous connective tissue. The side of the muscle nearest the eyeball quite often, but not always, becomes attached to the sclera by fibrous connective tissue. The process of repair

Fig. 3 (Chouké). Results of tucking on the thirty-fifth day. The tuck is seen in the center and the muscle on either side of the tuck connected by fibrous connective tissue. Under the left suture, attachment of the muscle to the sclera can be seen. H and E stain; $\times 25$.

tion of the muscle due to the formation of granulation tissue was a variable quantity."² He also found some adhesions between muscle and sclera 3 to 4 mm. posterior to the tuck. This is quite in agreement with the present observations noted above under the twelfth postoperative day findings. According to him: "Such adhesions might be expected to neutralize completely the effect of the tuck and possibly to limit motion in the field of the muscle." This comment by Gifford is significant and may explain, at least partially, the reasons for performing fewer and fewer tucking operations for strabismus

of extraocular muscles in the dog is essentially similar to that of the skeletal muscles elsewhere in the body. The time required for the completion of repair of extraocular muscles is slightly longer than that for general skeletal muscles of the same animal. The continuity of the muscle is preserved after the tucking operation, as evidenced by response to electrical stimulation.

The writer gratefully acknowledges the preparation of the microscopic sections by the Harrison Department of Research Surgery, University of Pennsylvania, under the direction of Dr. I. S. Ravdin.

CORNEAL DYSTROPHIES

ROBERT VON DER HEYDT, M.D.

Chicago 2

There has been much confusion in the ophthalmic literature in the description and classification of hereditary corneal dystrophies during the past 50 years.¹ Within the past decade Buecklers² initiated a first step toward an orderly classification by isolating three main clinically separate types. Twelve family groups consisting of 800 living in 35 small communities in Wuerttemberg were examined by Buecklers and his associate Gilch. Among these were 119 individuals presenting the three morphologically different types.

BUECKLERS'S TRIAD

1. *Dystrophia corneae granulosa* (Fleischer's type), "broeckelige," granular-disc form. This type may begin as early as the fifth year and progresses slowly until the thirtieth or fortieth year. Two family groups included 68 cases, showing dominance in heredity. The changes in this type are within a central disciform area. There is a clear marginal border. The individual lesions resemble dried bread crumbs in form. The slitlamp

shows the opacities in the areas of the interlamellar cement substance with no preference as to depth. The epithelium is rarely involved. However, I saw a case in 1925, which presented added superficial, definitely circinate lesions. I have seen a three-case group of a mother and two daughters. An interesting case of this type has been under my constant observation for over 20 years. The patient is now 50 years old. During this period, because of slow progression of the lesion, the vision dropped from 20/80 to 12/200. Castroviejo, 6½ years ago, performed a corneal transplant in this case. This granular disciform type is the most common among hereditary dystrophies. Buecklers in 1938 reported a histologic examination, and his conclusion was that the granular substance was a keratohyalin originating *in situ*.

2. *Dystrophia corneae reticulata* (Haab-Dimmer type), "gittrige," lattice. In 1898 Haab and Dimmer described the well-known lattice form of corneal dystrophy. It is composed of irregular double-contoured lines, often split at their ends.

They are in part superficial and glassy in character. In some of the cases which I have seen, there seemed to be a relative sparing of the pupillary area in the incipience.

I have seen three cases in one family at the Illinois Eye and Ear Infirmary, and two cases of a family group of father and five of eight adult siblings involved. Therefore, this type is dominantly hereditary. In the first three cases in one family the lesions were all large and coarse. In the second group the lines were faint and dainty in contour. These cases were sent to me for contact-glass trial. The vision in one eye was improvable from 20/120 with glasses to 20/30—3 with a contact glass. The patient was impressed, but not interested.

3. *Dystrophia corneae maculosa* (Groenouw type), *fleckige-knötchenförmige, spotted, at times nodular*. Groenouw first described a granular dystrophy in 1890 which later became known as the Fleischer type. During the same year he also described a spotted nodular type which bears his name. This initiated some of the confusion in the literature. These two types, the granular and nodular, were for some time designated as Groenouw type 1, and type 2 in European literature. In the Groenouw dystrophy the lesions begin early in the second decade of life as a diffuse spotting composed of faint, more or less rounded, superficial and deep cloudings. These extend to the limbus. They increase in number and density and later may become elevated and nodular, and by their interference may lead to practical blindness in old age. From his study Buecklers thinks the heredity is recessive. Family groups are not frequently found. I have seen only a few well-advanced cases of Groenouw dystrophy, more of moderate involvement.

Buecklers believes that each of these

three types of corneal hereditary dystrophy presents a definite clinical entity. He suggests that the term "familial dystrophy" as a description of all types be abandoned. Latin names were evolved descriptive of the three clinical types. The terms *granulosa*, *maculosa*, and *reticulata* were adopted in the Buecklers monograph.

FUCHS'S EPITHELIAL DYSTROPHY

This condition presents a chronic edema of the epithelium especially of the central corneal area. The cells are swollen and there may be droplets between them giving the appearance of glassy beads. It is similar to the slitlamp picture we see in glaucoma when the eyeball is under high tension. In old cases of Fuchs's dystrophy and in old glaucomatous eyes the epithelium develops a chronic degenerative vacuole formation. In Fuchs's dystrophy the central corneal epithelium presents this change because of the stromal imbibition of water derived from the aqueous. The great majority of epithelial dystrophies are secondary, owing to a senile cornea guttata. In these cases clear elevated humps protrude from the back of Descemet's membrane (Hassal-Henle Descemeti warts.) These humps elevate the endothelial cells. The raised endothelium is thus exposed to the trauma of the convection current within the anterior chamber. These elevated cells gradually degenerate. They lose their physiologic-barrier function, which normally keeps the aqueous from infiltrating into the corneal stroma. Pigment in the aqueous often attaches itself to this roughened, middle-posterior corneal surface.

A moderate amount of Hassal-Henle warts in the corneal center are a common senile slitlamp finding. When this formation becomes very pronounced the quite rare condition of Fuchs's epithelial dystrophy develops. There is no hyper-

tension. A few cases of Fuchs's epithelial dystrophy have been seen, with no visible endothelial changes or cornea guttata. These may present some as yet unknown dysfunction of the endothelial barrier. Meesmann has seen cases dominantly hereditary in which the endothelium appeared normal. This is difficult of determination, for the epithelial edema obscures the picture.

SALZMANN'S NODULAR DYSTROPHY

This type of dystrophy was first reported in 1925. It differs from Groenouw's in that the lesions are fewer and there is a vascularization. Vogt calls a similar condition keratitis tuberosa, and shows a typical case in his Atlas. The vascularization surrounds the nodules, but does not invade them. This is also shown in the illustrations of cases reported by E. V. L. Brown and Dewey Katz. Characteristic old corneal scars following phlyctenulosis are usually found in the same patient.

Five out of the 23 cases first reported by Salzmann were bilateral.

I have a kodachrome of a Salzmann nodular dystrophy in a man, aged 58 years, whom I saw over a year ago at Rush Medical Clinic. The patient was sent from the County Hospital. The condition was unilateral. There was a group of large elevated nodules. There was no vascularization, nor were there evidences

of old phlyctenular lesions. In this it resembled an advanced case of Groenouw's nodular dystrophy and could be so diagnosed, if it had been bilateral.

KERATOCONUS

Keratoconus is a corneal dystrophy, due to the development of a congenitally ordained central stromal weakness. The common lesions, conus formation, apical reflex, Fleischer's ring, Vogt stripes, superficial scar formation, and rupture in Descemet's membrane (the latter in only very advanced cases), are all due to the mechanical distortion incidental to the conus development. The clinical picture is well known.

I have a first edition of a book, probably the first one ever published concerning the cornea, entitled—"A treatise of the diseases of the horny coat of the eye," by Benedict Duddell, surgeon and oculist, published in London, in 1729. On page 32 there is given the first authentic description of conical cornea in the following words:

I saw a poor Boy at Hammersmith, that was blind of one Eye from Abscesses that had mined through the Blades of the Horney-Coat; and the Cicatrices following made a great Opacity, which hinder'd the Rays from Passing through the Coat. The cornea of his other Eye was swell'd out towards his Nose to the Bigness of half a Pea, and was transparent in the swell'd Part; the other Part of the Cornea was opaque; he cou'd see very well on that Side of his Eye next to his Nose.

DEFINITION OF ANOMALOUS RETINAL CORRESPONDENCE*

KENNETH C. SWAN, M.D.

Iowa City, Iowa

In a recent article on ocular terminology, Lancaster,¹ speaking for the American Committee on Optics and Visual Physiology, presented definitions[†] of anomalous retinal correspondence and related phenomena. One definition described an anomalous retinal correspondence as a condition in which the fovea of one retina and an eccentric element of the other acquired a common visual direction; that is, became corresponding retinal points. A review of the literature reveals this simple definition to be in common usage. Unfortunately, such a functional relationship between the fovea of the fixating eye and a peripheral retinal area in the squinting eye can be demonstrated in few patients with anomalous retinal correspondence. Moreover, attempts to use the definition as a criterion for diagnosis have misled some ophthalmologists to believe the anomaly rare. This fact is exemplified by a comparison of 100 cases

of esotropia selected at random from admissions to the State University of Iowa Clinics in 1935 with 100 consecutive cases admitted in 1942. Of the 1935 group, only three were suspected of having some anomaly of correspondence, whereas a definite diagnosis of anomalous retinal correspondence was made in 73 percent of the 1942 group. New criteria for diagnosis and improved methods of examination account for the discrepancy rather than does an increased incidence of the anomaly. In 1935, the orthoptist used an illuminated Brewster-Holmes type of prism stereoscope so adjusted that when one target was fixated by the fovea of the nonsquinting eye, the other target stimulated that peripheral retinal area of the squinting eye which, according to the aforementioned definition, could become a functionally corresponding point. Correspondence was considered abnormal only if the two objects

* From the Department of Ophthalmology, College of Medicine, State University of Iowa.

† *Corresponding points*: Points on the two retinas which have the same relative directional spatial value. For every point on the retina of one eye (except for the temporal crescent of each unocular field which is not included in the binocular field of vision, and except for the blind spot); there is a point on the retina of the other eye, stimulation of which gives the same sensation of direction. The foveas are the corresponding points *par excellence*.

Retinal correspondence is not an anatomic peculiarity innate and unchangeable. In squint, *anomalous correspondence* frequently develops. In this condition a different point of the retina of the squinting eye acquires a more or less perfect correspondence with a point of the nonsquinting eye. This is *secondary correspondence*, or anomalous correspondence. Another definition: If elements of the two retinas—for example, the fovea of one and an eccentric element of the other retina—acquire a common visual direction, this new sensorial relationship is termed anomalous or secondary.

Angle of anomaly (Bielschowsky), *angle of adaptation* (Chavasse): When an eye has deviated a long time, a certain amount of adaptation may take place. The fovea of one eye no longer has the same directional value as the fovea of the other eye, but instead some peripheral point of the retina of the deviating eye acquires a directional value corresponding to the fovea of the fixating eye. This is secondary or anomalous correspondence. The angle between the line of direction of the fovea and the line of direction of this new point, which corresponds in directional value with the fovea of the other eye, is the angle of adaptation or the angle of anomaly.

Harmonious correspondence. If the angle of anomaly or of adaptation is equal to the angle of deviation, the secondary correspondence (anomalous correspondence) is called harmonious. The point of the retina of the deviating eye on which the image of the point of fixation falls is the point that has acquired correspondence with the fovea of the fixating eye. Sometimes (often) it is not this point but some point between it and the fovea that corresponds with the fovea of the fixating eye. Then the correspondence is subharmonious (Chavasse).

were perceived as superimposed; a finding that was rarely recorded. The fallacy of the test and consequently of the definition became evident when determination of the field of binocular vision became a routine procedure.

Several methods were used to plot the field of vision of the squinting eye while the patient maintained fixation and a full field of vision in the other eye. In one method, a mirror placed before the fixating eye separated the fields of vision. While this eye fixated a centrally placed target on one tangent screen, the field of vision of the squinting eye was plotted with 1- to 5-mm. white targets on a separate unmarked screen at distances of one to two meters. In another method, colored filters were used to separate the fields of vision of the two eyes. A red filter was placed before the fixating eye, and for fixation a small red disc of light was projected upon an unmarked white wall at distances of two to six meters. A green filter was placed before the squinting eye, and a tiny green disc of light was projected on the screen at various positions to plot the field of vision of the squinting eye. The patient was required to distinguish only the presence of the peripheral image, not its green color. The stereocampimeter provided a third method of examination.

With all methods it seemed that, in accordance with the findings of Travers,² the point of fixation was perceived only by the fixating eye in almost all cases of untreated nonparalytic esotropia. For example, patients with anomalous retinal correspondence described the target presented to the squinting eye as approaching the point of fixation, disappearing, and then reappearing on the opposite side. Rarely was the target described to be superimposed on the fixation point. This finding made evident the fallacy of applying the aforementioned definition to the diagnosis of anomalous correspondence.

How could the fovea of the fixating eye become a functionally corresponding point with a suppressed retinal area in the squinting eye?

Verhoeff³ believes that both eyes, and particularly the two foveas, are habitually used simultaneously by squinters who are free from amblyopia. In almost every case of esotropia the field of vision showed some degree of suppression of the macular region of the squinting eye; however, excluding those patients with extramacular fixation and a large absolute central scotoma in the monocular field of vision, the macular region was found to retain a relatively high degree of form sense (equivalent to 5/60 to 6/21). Moreover, it was usually possible to demonstrate whether or not this partially suppressed macular area of the squinting eye retained the same visual direction as the macular region of the fixating eye. If objects were presented simultaneously to both maculas, the patient with esotropia and anomalous retinal correspondence had crossed diplopia with images separated by an angle approximating or slightly less than that of the squint; with normal correspondence, the images were superimposed. A number of tests for anomalous correspondence have been applied on this basis; for example, the after-image test of Tschermak.⁴ All are so devised that when the macular regions are stimulated simultaneously, the patient is able to distinguish between the images of the two eyes and to visualize their relative visual directions. In recent years three methods of determining retinal correspondence have been used in the Iowa Clinic: afterimages, stereoscopic devices, and a projection system with color or polaroid filters.

These three types of tests do not always agree, but this is not an indication that one or the other test is incorrect or that the criterion for diagnosis is inadequate; rather it is an indication that correspond-

ence is variable. The abnormal relationship between the central retinal areas of the two eyes often is fixed at a constant angle (angle of anomaly), but in some patients, particularly those who have received treatment, it may be variable or even absent, depending upon the circumstances under which the test is performed. For example, in monocular squints it is not rare to find normal correspondence when the usually squinting eye is forced to fixate, but anomalous correspondence under other conditions. The correspondence also may vary with the intensity of the stimulus and the total area of the retina stimulated. Finally, anomalous and normal retinal correspondence frequently coexist in patients receiving treatment; that is, monocular diplopia in the squinting eye. This variability becomes evident only when more than one type of test is used routinely. It is one of the important characteristics of anomalous correspondence.

Anomalous correspondence tends to adapt itself to the deviation of the squinting eye. This fact is important, for it is another prevalent concept that simple changing of the deviation of the eyes by muscle surgery constitutes effective treatment. In the author's experience, this concept is erroneous. Several years ago nearly 100 esotropias with abnormal correspondence were corrected to within a few degrees of orthophoria by surgery. After a period of two to four months, the large angle of anomaly had disappeared in the majority of cases, but it was seldom possible to demonstrate fusion* developing either spontaneously or after intensive orthoptic exercises. The failure to establish true fusion in most of these patients was explained when they were reexamined and especial care was used to stimulate exactly the foveal regions. Anomalous correspondence with variable angle of anomaly of only a few degrees

was repeatedly demonstrated. Moreover, it was exceedingly difficult to establish normal correspondence in these patients by orthoptics; the angle of anomaly was so small that it was practically impossible to adjust any instrument to stimulate simultaneously the desired retinal areas without at the same time stimulating the anomalously related areas. Prolonged occlusion (4 to 12 months) was also unsuccessful. Repeated examinations made during the past five years with an additional control group of 100 patients with abnormal correspondence treated surgically without orthoptics or occlusion provided further evidence that anomalous retinal correspondence tends to adapt itself to the deviation of the eyes; that is, a new variable angle of anomaly approximating the deviation of the eyes develops over a period of months. Therefore, when surgery is performed as an initial procedure in patients with anomalous retinal correspondence, immediate and intensive postoperative orthoptic exercises are desirable to establish normal correspondence and fusion before the anomalous correspondence *adapts itself to the new deviation*.

Pugh⁵ has advocated the therapy outlined; that is, surgery followed immediately by intensive orthoptic training. The writer has found it more expedient to utilize another characteristic of anomalous correspondence; that is, its instability with disuse. Not infrequently the anomaly is disrupted by occlusion of one eye for several months. Prolonged occlusion is an essential first step in some cases, and in all instances shortens the period of supervised orthoptic training. Dicke⁶ has also advocated a program utilizing preoperative occlusion.

DISCUSSION

Perhaps a definition of anomalous retinal correspondence need only include a correct example of the anomaly; for ex-

* Maddox Grade II.

ample, the definition of Bielschowsky⁷: "The foveal images of the two eyes are not localized as in cases with normal correspondence in one and the same visual direction, but in different directions coinciding with the geometrical (foveal) lines of direction." However, mistakes such as those described will be generally fewer if the definition includes those outstanding characteristics of the anomaly which must be understood for proper diagnosis and treatment.

Objections to the definition in common use are summarized, and a new definition is presented including those characteristics that in the writer's experience are essential to proper diagnosis and treatment of anomalous retinal correspondence. Possibly there are other characteristics that should be included.

SUMMARY AND CONCLUSIONS

The prevalent definition of abnormal retinal correspondence as an anomaly in which the fovea of the fixating eye and a peripheral retinal area in the squinting eye become functionally corresponding points seems erroneous. Studies of the field of binocular vision reveal that the peripheral retinal area in question is almost invariably suppressed.

Unless there is a high degree of amblyopia the macular region of the squinting eye is only partially suppressed; consequently, demonstration that the foveal or macular regions of the two eyes are not corresponding points provides a prac-

tical method of diagnosing anomalous retinal correspondence in the great majority of patients. Afterimages, stereoscopic devices, or a filter projection system may be utilized to stimulate the macular regions and to determine their relative visual directions.

Anomalous retinal correspondence is not necessarily fixed at a constant angle of anomaly, but is frequently variable and tends to adapt itself to the deviation of the eyes. Experience with several hundred cases indicates that instead of completely disrupting abnormal retinal correspondence, muscle surgery alone usually results in a gradual change in the angle of anomaly to correspond with the new deviation.

Another characteristic of anomalous retinal correspondence is that it becomes unstable with disuse; that is, disruption of binocular vision. Prolonged monocular occlusion is an important adjunct in treatment of the anomaly.

In accordance with these findings, anomalous retinal correspondence is defined as an anomaly of binocular vision in which areas in the two retinas normally having a common visual direction—for example, the foveas—acquire an unstable and often variable visual direction in relation to each other but usually in accordance with the squinting position. The anomaly is always associated with some degree of suppression of the squinting eye, the point of fixation almost invariably being viewed monocularly.

THE USE OF CHOLINE IN CASES OF ULCER AND OF LEUKOMA OF THE CORNEA*

THEODORE J. DIMITRY, M.D., AND PAUL AZAR, M.D.
New Orleans

It may be that in the early days of medicine the term *cataract* was applied to any obscuration of vision, even to pathologic change in the innermost layers of the retina. The word *cataract* is derived from the Greek *kata*, down, and *arassein*, to fall. Anything that fell over and in front of the percipient elements of vision was to the people of that time a *cataract*.

In this more enlightened age we have appropriated the word to designate a pathologic condition of the crystalline lens. It is not unusual for even cultured individuals, those in the habit of analyzing words, to become confused when the word is applied to a particular pathologic state, for individuals forget that words are only arbitrary.

The subject of this contribution concerns the white cicatrices of the cornea and the ulcer responsible for such scars. It is desired to show that these ulcers can be aborted and that the agent used to this end can also be adopted to treat the scar that the ulcer leaves. It might have been preferable to present for consideration merely the bare facts and the simple demonstration and to leave speculation to the reader; however, it is not entirely possible to do so. The subject of choline must be treated somewhat more fully.

We appreciate the fact that scars of the cornea often diminish from childhood to adult life and that it is possible for man to imitate senescence in a scar and thereby reduce its size. How this is done is usually a matter of speculation. We

hope to demonstrate the action of choline on such scars.

Long ago bile was instilled into the eye to affect scars of this kind. We submit that a constituent of bile is the agent that induces the amelioration. Although bile contains but a small amount of this constituent—namely, choline—we are of the opinion that it may be the factor that accomplishes the desired results.

Choline will, in a remarkable manner, cleanse a moderate-sized corneal ulcer of pus, leaving the floor of the ulcer clear. Should the ulcer penetrate the cornea and there be pus in the anterior chamber of the eye—limited, however; not a panophthalmitis—choline will find the channel and search out the pus without injuring the tissues. Its performance is uncanny. Choline dissolves fibrin. It will “turn over” lipoids and cholesterol esters in cases of corneal leukoma, reducing the size of the leukoma.

We are not concerned here with determining whether choline is or is not, constitutionally, a vitamin, a vitagen, a hormone, or an enzyme; whether it is anti-hemorrhagic, lipotropic or what its effect on cholesterol esters is; we are interested in the fact that when applied topically to an ulcer of the cornea the pus is purged; when applied to a leukoma the cicatricial disfiguration is reduced. We have treated numerous ulcers of the cornea sufficiently to convince ourselves of its effect.

In the treatment of leukoma the results are most encouraging, but less spectacular than in the case of ulcers. We first test with fluorescein to discover if there is epithelial abrasion. Usually there is not.

* From the Department of Ophthalmology, Charity Hospital of Louisiana.

Then choline is instilled, followed by another test with fluorescein. The epithelium for the second time does not stain. However, the periphery of the leukoma does. In view of this evidence we conclude that choline has the power to penetrate the epithelium of the cornea and enter the corneal stroma. At first the direction of penetration is like ripples about the lesion, the action to be expected from a wetting agent; secondly, choline penetrates into the anterior chamber of the eye, the action one would expect from a polar, nonpolar chemical. If the lesion extends to the lens the course of the pathologic process will stain; however, we have not as yet been able to stain vitreous opacities. We have flooded the anterior chamber with a 1-percent solution of choline and without injuring the tissues.

Lipoids and cholesterol esters in scars of the eyes have been accorded very little attention in the past. Yet they are, in our opinion, of great importance in maintaining persistence of disease. Mustard-gas lesions of the cornea are an example of an irritation maintained by lipoids and cholesterol crystals. Choline changes lipoids into phospholipoids. The latter can be readily removed from the lesion and this is probably true of cholesterol esters also.

The action of choline upon pus will not be discussed here except to state its purging effect. It will liquefy pus in the test tube as well as fibrin and other substances.

Many chemicals have been applied to leukomas to reduce their size, but few have merit. Dionin is one of these. It is not lipotropic; choline is. Histologically, scars have been carefully studied, but only as static tissues; not as lesions in a functioning organ of multiple chemical processes in which there is incessant

change. One does not question the exact studies of the pathologist as regards static tissues, but his studies of lipoids and cholesterol in these tissues are not so careful; in fact, he destroys them.

The properties of choline, chemically, biochemically, and physiochemically, are deserving of attention.

Choline was probably first isolated fully 100 years ago, the original source being from the lecithin of liver secretion. It is a simple natural organic base and its chemical formula is as follows: $C_5H_{15}NO_2$, with a molecular weight of 121.13. It has a white color and a fishy odor. Synthetically it may be obtained by treating an aqueous solution of trimethylamine with ethylene oxide.

Choline is a strong base liberating ammonia from its salts and precipitating as hydroxide (from aqueous solution) the salts of the heavy metals. Its solution dissolves fibrin and prevents the coagulation of proteins. It appears that choline is involved in the metabolism of cholesterol as well as in that of the neutral fats.

Physiochemically, it is one of the most remarkable penetrating agents. Its molecule is both polar and nonpolar, and is soluble in either water or oil. It will readily combine with other drugs and staining agents and carry them deep into the tissues.

SUMMARY

Choline is a most promising agent in the treatment of ulcers of the cornea and of leukoma of the cornea. It should be applied topically in such conditions.

NOTES, CASES, INSTRUMENTS

INTRAOCULAR INJECTION OF PENICILLIN IN A CASE OF RING ABSCESS OF THE CORNEA

DAVID ROBERT ALPERT, M.D.*

Boston

Ring abscess of the cornea has always been a disease characterized by a poor prognosis and usually has resulted in perforation of the cornea with loss of the eye. The excellent results obtained by the use of penicillin injected into the anterior chamber and associated sulfadiazine therapy warrants the recording of this case of ring abscess.

CASE REPORT

D. G., a woman, aged 29 years, was first seen at the Boston City Hospital Emergency Floor on January 23, 1944, complaining of photophobia, lacrimation, and pain in the right eye. The patient stated that on the previous day a foreign body had been removed from the corneal area by the use of a "clean handkerchief." On examination, a small localized ulceration was observed on the right cornea, with associated ciliary and conjunctival injection. No foreign body was present. Local therapy of warm boric-acid-solution compresses, White's ophthalmic ointment with 1-percent atropine, and a sterile dressing was advised.

On January 24th the patient reported to the Out-Patient Department with markedly increased severity of her symptoms. An ulceration, measuring 3 by 5 mm., with deep infiltration was found at the 3-o'clock position. Moderate ciliary congestion existed, and the iris was fully dilated. Tension was palpably soft, with

slight deep tenderness. Visual acuity at the time was O.D. 20/40, O.S. 20/30. The previously advised therapy was continued, the applications to be made at more frequent intervals.

Two days later the patient was seen in the Out-Patient Department. The ocular condition was found to be alarming, and admission to the Hospital was advised. A culture and smear of the cul-de-sac of the right eye were taken at 9:00 A.M. and later proved to be *B. pyocyaneus* and hemolytic *Staphylococcus aureus*.

Physical examination. The patient had an oral temperature of 101; pulse of 95, and respirations of 20 per minute. She was flushed and complained of chilliness. General physical examination revealed no other abnormalities; her blood pressure was 120/80.

Right eye. Erythema and slight edema of both lids were present, together with an almond-sized, tender, preauricular lymph node. Lacrimation and purulent exudate were profuse. No material was expressed from the lacrimal sac. The ciliary and bulbar conjunctival injection was intense and diffuse. There was no elevation of tension to fingers, but ocular tenderness was present. The cornea was opaque in its entire central area; a small rim of clear cornea approximately 2 to 3 mm. in width persisted between the lesion and the limbus. The clear area became narrower toward the nasal half of the cornea at the site of the original lesion. The involved corneal tissue was of blotter-paper appearance and stained readily with fluorescein solution. This area was opaque; a hypopyon filling one third of the anterior chamber was visible through the clearer areas. A distinct groove in the corneal surface, most marked on the nasal side, was present at the margin of the le-

* Now Lieutenant (MC) A.U.S. Formerly Resident Ophthalmic Surgeon, Boston City Hospital.

sion just proximal to the clear corneal area. A hazy outline of a dilated iris could be made out. Only light perception and projection could be elicited, but these were normal. Ocular motility was normal.

Left eye. External and fundic examination of this eye was entirely without pathologic findings.

The patient had had no significant illnesses nor familial diseases pertinent to her present condition. She was married, the mother of three children, and had always enjoyed good health. There had been no visual impairment nor previous ocular complaints, except that one month previously she had removed a minute foreign body from the cornea of the right eye, but without subsequent discomfort.

Diagnosis: 1. Ring abscess of the cornea, O.D.; 2. Hypopyon, O.D.

Therapy. The acuteness and gravity of the ocular picture warranted immediate and intensive therapy. The culture was repeated from the right cul-de-sac, and the organisms were the same as those previously found (*B. pyocyaneus*, hemolytic *Staphylococcus aureus*).

Fifteen million organisms of typhoid-vaccine diluted to a volume of 1 c.c. in physiologic saline (0.85 percent) were given intravenously. Although the temperature, pulse, and respiration readings were recorded hourly, no reaction was observed.

Simultaneously, oral sulfadiazine was administered. The initial dose of 2 gm. was followed by 1 gm. every four hours.

Hot boric-acid-solution compresses were instituted for the right eye, for a 10-minute interval every hour. Each hour 5-percent sulfadiazine ointment was instilled and followed by the application of a dry sterile dressing.

The Ophthalmic Service of the Boston City Hospital had had no previous experience with the use of penicillin in ocular conditions, but was granted the use of

50,000 Oxford units. An isotonic saline dilution of 250 units per c.c. had been suggested¹ for topical use. No literature nor information was available as a guide at the time in the intraocular use of penicillin, but, in view of the rapid progression and poor prognosis of ring abscess of the cornea, further delay was not warranted.

At nine o'clock on the evening of January 26th, and with observance of sterile operative technique, the right eye was prepared and local topical anesthesia obtained with 0.5-percent pontocaine. A saline solution containing 250 units per c.c. was prepared from the powdered, sterile, vial-contained penicillin. An empty 1-c.c. syringe fitted with a short, sharp needle was introduced at the limbus at the 3-o'clock position and directed toward 6 o'clock, according to a technique described by Igersheimer.² Care was taken to avoid the iris and prevent the needle from striking either the posterior corneal surface or the anterior lens surface. Approximately 0.3 c.c. of turbid aqueous was withdrawn. Leaving the needle in place, the syringe was detached and the contents emptied into a sterile culture tube. Another syringe was then partially filled with penicillin solution, reattached to the needle, and 0.3 c.c. (± 75 units) was injected into the anterior chamber. The needle was withdrawn rapidly, and the conjunctival sac and cornea were flushed with 1 c.c. of penicillin solution. A dry sterile dressing without ointment was applied, and the patient was returned to the ward.

Because penicillin is altered at temperatures higher than 5°,³ the prepared solution was placed in a refrigerator. It had seemed advisable to warm the syringe containing the penicillin in the palm of the gloved hand before the injection was made, lest the tissues fail to tolerate the chilled solution.

The culture report of the aspirated aqueous proved to be hemolytic *Staphylococcus aureus*.

Subsequent local therapy consisted of hourly hot boric-acid-solution compresses followed by a direct application of 1 c.c. of penicillin solution, drop by drop, to the cornea.

On January 27th the cornea showed slight improvement in that the density of the central yellowish opaque area had diminished, and thinning out seemed to appear superiorly. The corneal groove persisted. The hypopyon had lessened. A dilated pupil was more easily visualized, and the tension remained soft. Repetition of the intraocular instillation of penicillin seemed advisable and was performed. The procedure was identical, but culture of the aspirated fluid resulted in no growth!

On the following day a definite improvement was noted, with the absence of an hypopyon and a thinning of the central opacity, which had taken on a less necrotic appearance. Dr. Josef Igersheimer saw the patient in consultation and agreed with a diagnosis of ring abscess.

On January 31st progressive improvement of the corneal lesion was observed to have continued. The peripheral clear cornea persisted, and the density of the opacity lessened, receding toward the center. No synechiae were observed, but the pupil was kept dilated by instillation of one drop of 1-percent atropine sulfate solution on alternate days. The tension remained soft. The ciliary congestion persisted.

The oral administration of sulfadiazine was reduced to 4 gm. daily. Penicillin solution was then omitted between the hours of 12:00 midnight and 7:00 in the morning, 5-percent sulfathiazole ointment being used for the last dressing of the day.

Culture from the cul-de-sac showed no growth.

On February 2d, lessened ciliary con-

gestion and ocular tenderness were observed. The ulceration stained with fluorescein was one-half its original size and was located slightly eccentrically to the nasal side. A crescent-shaped, non-staining furrow remained at the 3-o'clock position within the opaque but not ulcerated area.

Local therapy was reduced to three-hour intervals during the day.

Five days later only a 2-mm.-diameter area took the stain. No synechiae were visible. The entire area of involvement appeared as a dense opaque area with the same clear periphery. Vision had improved to the perception of fingers at four feet.

The allotted penicillin was exhausted, but local sulfathiazole ointment was substituted. Oral sulfadiazine was continued. The blood sulfadiazine level on February 4th was: free = 2.3 mg. percent; total = 2.6 mg. percent. The blood Wassermann report was negative.

On February 10th, the lesion was completely healed with a resultant dense central corneal scar. The patient was discharged to the Out-Patient Department and advised to use White's ointment and to continue the application of warm compresses.

The patient was seen in the Out-Patient Department on February 14th, 21st, and on March 6th, and showed subsiding congestion and constant visual improvement. On March 6th, her vision O.D. was 10/200, and the eye was white and quiet. The pupil was active and without synechiae. Tension remained normal to palpation. By slitlamp, the corneal opacity was observed to involve the entire thickness of the substantia propria; it was covered by smooth epithelium. Peculiarly enough, the demarcation of the scar was equal to the extent of the corneal involvement at the height of the disease. It had a disciform appearance surrounded by clear

cornea; the density of the opacity varied in different areas. The nasal furrow persisted as part of the border of the scar. Several fine deposits remained upon the anterior capsule of the lens.

An ointment containing 2-percent yellow oxide of mercury was prescribed to be applied four times daily to stimulate resorption of the scar.

COMMENT

A case of ring abscess of the cornea has been presented wherein dramatic therapeutic results were obtained with the local extraocular and intraocular use of penicillin plus oral sulfadiazine. The cases of recovery of ring abscess which have been reported are few. No such case has come to the author's attention in which penicillin was employed as an intraocular instillation.

The use of a saturated solution of sulfanilamide (0.8 percent) as an injection into the anterior chamber has been reported in a case of purulent iridocyclitis.² This solution was tolerated well by the tissues but one could not predict the effect on the tissues of a solution of penicillin. "Penicillin"* supplied as the sodium salt

of penicillin was dissolved in normal saline, from which a yellow-tinged solution (250 units per c.c.) was obtained. Approximately 0.3 c.c. (± 75 units) was instilled. Local hourly irrigation was performed with the same solution. It was necessary to repeat the intraocular instillation 24 hours later. The astonishing subsidence of the process, disappearance of the hypopyon, and negative culture evidenced the therapeutic effect. The solution was well tolerated by the tissues; no synechiae have remained and the lens is clear. Only a deep scar of the cornea remains involving the tissue to the extent of the original lesion.

The organisms obtained were hemolytic *Staphylococcus aureus* from the anterior chamber and cul-de-sac, *B. pyocyaneus* from the cul-de-sac.

The effect of the sulfadiazine as against that of penicillin in this case cannot be debated. The aim was a therapeutic result and the gravity of the situation demanded that all agents at hand be used. One can conclude, however, that penicillin was well tolerated by the tissues in the concentration employed for intraocular instillation.

Iontophoresis has supplanted the need for intraocular injections in many instances. The fact that the apparatus, simple as it may be, is not possessed by all institutions, may necessitate anterior-chamber instillation of penicillin.

MYXOMA OF THE LOWER EYELID

ARNO E. TOWN, LT. COMDR. (MC),
U.S.N.R.

Bethesda 14, Maryland

Mixed tumors of the eyelid with the typical structure of the lacrimal gland are common, about 256 having been reported, but, in so far as it was possible to ascertain, no previous reports of a myxoma of the lower lid composed of the structure of a sweat gland have been made.

In the thirteenth annual report of the Memorial Ophthalmic Laboratory, Giza, Cairo, there is published a case of a mixed tumor of a sweat gland of the eyelid. It occurred just above the inner canthus of the left upper eyelid, and was about 2 cm. in diameter. It was encapsulated and was easily shelled out. Microscopically it had the typical appearance of a mixed-cell tumor of the salivary-gland type. The component cells were rounded, cubical, spindle shaped, and angular, arranged in islands and branching strands. Some groups of cells had a glandular arrangement. The stroma was loose and cellular and in many places there was evidence of mucin formation, giving rise to the appearances of mucoid or myxomatous connective tissue.

Mixed tumors may also develop in regions removed from lacrimal glands, salivary glands, and the like. They occur in the pharynx, on the lips, and other sites.

As to their origin, there are many opinions, which may be grouped into two theories: the one proposing a conjunctival origin, the other proposing an endothelial origin. Other authors attribute to these tumors a mixed ciliary epithelial origin.

Regarding pathogenesis, the majority of writers are in agreement in considering these tumors to be derived from disturb-

ances in development. Some believe that the tissue of the tumors is the result of a proliferation of the already developed glandular tissue; the glandular lobules change into new lobules whose septa of connective tissue are developed from previously existing septa. This accounts for the lobular structure of the tumor.

CASE REPORT

A woman, aged 39 years, had noticed a small growth near the inner angle on the left lower lid for two months prior to consultation. Examination revealed a small mass surrounding the left lower punctum, elevated, and with a glassy cystic appearance. The punctum and canaliculus were patent. The tumor was not encapsulated and at the time it was dissected from the lid, it was difficult to determine the line of demarcation from the orbicularis muscle. The wound was closed with black-silk sutures and healing was uneventful.

PATHOLOGIC REPORT by Algernon B. Reese, M.D.: *Subject*, Myxoma of the eyelid; specimen from margin of the left lower lid. *Stains*: hematoxylin and eosin, trichrome, mucicarmine.

The specimen consists of two fragments of tissue both of which are covered on one side by a layer of stratified epithelium showing slight tendency toward keratinization along the surface. The nuclei of the basal layer are more darkly staining and cylindrical. The one piece consists almost entirely of tumor tissue extending from the corium into the deeper tissue, where it infiltrates between striated muscle fibers. The cells of this tumor are stellate and contain a nucleolus which varies a great deal in size and shape, stains lightly with hematoxylin, and has a diffuse almost homogeneous distribution of the chromatin. There is a scanty amount of faintly eosin-staining proto-

Fig. 1 (Town). Myxoma of the lower-lid margin ($\times 350$).

plasm and a coarse, wavy fibroglia structure. The main characteristic of the tumor, though, is the intracellular substance, which stains faintly blue with hematoxylin, faintly pink with mucicarmine, and faintly red with trichrome. In places it is almost homogeneous but at most sites it contains a fine fibrillar structure. This intracellular substance seems to compress the nuclei and fibroglia. Immediately beneath the epithelium, the nuclear elements are much greater and the intracellular substance less, so that here the tissue more closely resembles the usual connective tissue. There is no tendency to encapsulation, but the tumor borders have rather poor demarcation due to its gradual infil-

tration into the surrounding structures.

The second piece of tissue is composed almost entirely of a normal-appearing connective tissue in which is striated muscle, a hair follicle, and some rudimentary glands that seem to resemble the sweat-gland type. Beneath the epithelium at one site is some tumor tissue which resembles that described in the first specimen.

Diagnosis: Tumor of lid—myxoma, probably derived from the intermuscular connective tissue.

Drs. A. Purdy Stout, Fred Stewart, and Hillman have examined this specimen and concur in the diagnosis.

BURNS OF THE EYELIDS AND CONJUNCTIVA

SURGEON REAR ADMIRAL CECIL WAKELEY, in opening the discussion, said that the problem of burns of the face and eyelids has been a very important one during this war as well as the last war. In the last war, in the navy, there were over 6,000 cases of burns, 95 percent of which affected the face and hands. In the services, whether in the airplane, the tank, or the large or small ship, the face and hands suffer most severely. The first-aid dressing in those days was picric acid, but the cases showed that this was of no use whatever, because when put on and left there, it coagulated the skin to such an extent that a second-degree burn was converted into a third-degree burn when the dressings were removed.

In 1916 it was realized that there were two fundamental things in the treatment of burns: (1) elimination of sepsis; and (2) skin grafting for the third-degree or deep burn.

Soon after the beginning of this war there was an undue number of facial burns which were the result of the men having the face completely unprotected. At the end of 1939 extra protection was devised for men who did not wear a gas mask. It consisted of cellulose acetate goggles and aertex heat-resisting material

for the nose and mouth. This protective device markedly decreased the incidence of burns of the face. The greatest proportion of cases are produced by exploding bombs. The bomb may not have touched the patient at all, but the effect of the blast is to split the skin, and produce a superficial burn of the hair and face. There are usually other lesions as well. Patients have been successfully treated with triple-dye jelly.

In a bomb flash burn the blast may also cause the skin to split. Some of these lesions of the skin penetrate a quarter of an inch, but the face is so vascular that practically no scarring is experienced from the effect of such burns, and there is no permanent disability.

In the treatment of burns, there is a vast difference between the case which is brought to the hospital within an hour of the accident and the case which does not reach the hospital for five or six days. In the Royal Navy at the present time 50 percent of the casualties due to burns occur on smaller ships which have no medical officers on board and often cannot reach port for five or six days. In 1939-1940 one half of these patients died. By the time the men reached the hospital they were moribund. The use of tannic acid was abandoned and a coagulant such as the triple dye or gentian violet was used and the mortality rate was reduced to 5 percent.

At the beginning of the war it was thought that every case of burns should have intravenous plasma, or saline. At the present time only 1 out of 10 is given intravenous therapy and that is due to the fact that this method has been replaced by the intake of fluids by mouth.

Shock. He said that in the opinion of the Navy morphia will never kill a man who is in pain. As to the application of heat in shock it has been stated that the clinician is apt to overheat his patients who are suffering from shock. This may be true in some cases, but he said he has never seen a patient who was badly shocked suffer from too much heat. As soon as the patient's clinical condition has returned to normal the heat should be reduced.

Wing Commander J. C. Neely said that an analysis of 120 cases of burns received at an R.A.F. hospital showed that in 80 percent the face was affected, and, of this number, 20 percent had ectropion and 5 percent had the globe affected. The causes of these types of burns were: (1) petrol flames, incendiary and flash bombs; and (2) caustic acid, alkalis, and gaseous chemicals. The goggles which were first issued were inadequate because of their restricted visual fields. These have been modified according to the specifications of Air Commodore Livingston and now offer a very wide field of vision.

Flight Lieutenant D. C. Bodenham said that, as had been pointed out, in war burns of the face due to exposure to flame the eyelids were very frequently involved. He stressed the importance of the sebaceous glands and hair follicles of the skin, because in destructive burns there were invariably isolated epithelial cells left in the dermis and it was from these island cells, by spreading and coalescing, that healing occurred.

The two types of burns, important from the point of view of treatment, were the superficial second-degree burn affecting the epithelium only, and the destructive or third-degree burn in which all or practically all of the dermis was destroyed. But it was surprising how often epithelial glands survived and were suffi-

cient to bring about the healing of small areas, although in the case of extensive destruction this was much too slow, and skin grafting was necessary.

He showed a case of a typical second-degree burn, saying it would heal with very little trouble, almost without treatment, and would present practically no problem provided it was kept clean.

The real problem was the destructive third-degree burn, with the epithelium hanging in loose shreds, exposing the underlying dermis, which was coagulated. No treatment would entirely prevent scarring in these cases.

In facial burns, because of the very loose supporting tissues, a tremendous amount of edema developed even with a moderate burn. The edema appeared a few minutes after the accident and increased up to 12 hours. It remained at the maximum from 12 to 36 hours and then began to subside.

In the Air Force there were only a few flash burns. These burns were due to the instantaneous combustion of magnesium used in flash bombs. In these the exposure was a matter of a fraction of a second, whereas in the flame burn it was anything from 10 to 60 seconds, and permitted a chance to close the eyelids, which tended to save the globe at the expense of the lid. In the flash burn, although there was conjunctival involvement, the exposure was so brief that the burn was largely superficial. The globe in these cases was somewhat protected by the constant film of moisture which bathed the cornea and the conjunctiva.

In magnesium flash burns tattooing of the globe sometimes occurred, owing to minute particles being driven into the globe by the force of the explosion. Unfortunately they were often too small and too numerous to be removed surgically. Though the skin of the eyelid was particularly delicate, it was surprising how,

even in the worst burns of the eyelids, the tarsal plates remained intact.

Treatment. In the Royal Air Force the results with tannic acid were so unsuccessful that quite early in the war its use was forbidden. The present-day treatment rested on simple principles; namely, to prevent infection and to do as little harm as possible to the healing tissues. If infection developed it should be treated specifically. Early healing should be the aim and, if necessary, it should be assisted by skin grafting. For some 18 months, he said, they had been using the synthetic detergent, cetyl trimethyl ammonium bromide. It was used in 0.75-percent water solution and was a very good anti-septic. It combined many valuable features for the primary cleansing of fresh burns. It was applied with a swab of cotton-wool. Any loose-hanging threads of epithelium were removed. Cleansing was followed by an application of sulphonamide, either powder or 3-percent cream. The face was covered by coarse mesh vaseline gauze, and this made a very soft, gentle, nontraumatic dressing, and one which could be easily removed.

Facial burns were particularly open to infection. The nose and mouth could not be completely covered and formed an adjacent source of staphylococci and streptococci, which obtained easy access to the burned tissue; in this way infection, particularly staphylococcus, occurred almost always in the treatment of these severe burns. Penicillin had been used as a local application. If it was used in a cream base he said he preferred a simple mixture of lanette wax and vaseline. Penicillin, made to a strength of 100 units per gram, was consistently effective in eliminating streptococci and staphylococci from granulating surfaces. It was applied every 24 hours, and the cases as a rule responded within four days. In undertaking specific treatment, he said they often reverted to

penicillin because of the failure of the sulphonamides. In this way they obtained the conditions under which healing took place most rapidly.

Later when contracture of the lids developed, keratitis was not infrequent, and might result in ulceration with loss of the eye, though this had not occurred in his experience. In the milder cases simple measures might be employed, such as constantly keeping the globe moist with saline and using a lubricant like liquid paraffin. In the severe cases with complete ectropion which developed before the face and lids had healed, this alone would not prevent keratitis. A patient was shown wearing a contact lens.

Effective protection to the cornea could be given much more simply by wearing a standard anti-gas shield. These eye shields were particularly valuable in protecting the cornea when such cases came to operation for skin grafting of other areas.

They could be used with complete confidence and many sore eyes could be avoided by this simple measure.

Squadron Leader G. W. Cashell said that it was interesting to note that in the R.A.F. type of burns of the face it is unusual to find any burning of the cornea or conjunctiva. The lids, which were instinctively closed, bore the brunt of the trauma, and in the majority of cases there was only some slight reddening of the conjunctiva, and slight edema of the corneal epithelium.

Cases of direct burning of the conjunctiva have been due to: (1) a magnesium flash bomb; (2) incendiary bomb; (3) the effect of phosphorus; and (4) concentrated sulphuric acid.

In treating cases where the conjunctiva and cornea were directly involved, the important thing was the prevention of adhesions between these two structures, or between the palpebral and ocular con-

junctiva with obliteration of the fornix. It was much easier to prevent these complications than to deal with them.

He reported details of five cases. The points to be noted with regard to these special types of burns were; (1) control of infection; (2) prevention of symblepharon, which could be guaranteed by the use of a rapidly made plastic contact lens; and (3) mucous membrane could be used to restore the conjunctival fornix, where obliteration had occurred, and was less irritating than skin.

Mr. T. Pomfret Kilner confined his contribution to the showing of a film which indicated clearly the technique of eyelid grafting. This seemed all the more justifiable since a very high percentage of the repair work on burns about the eyelids is concerned with the treatment of ectropion.

He advised that when possible only one eyelid should be operated on at a time; that it was unwise to graft upper and lower eyelids at the same operation, for if this were attempted, it would be difficult to obtain over-correction, on which success so much depended. He said that approximation of eyelids by tarsorrhaphy and grafting both eyelids with a single mold-applied graft failed to give the necessary area of new skin, reëversion of the eyelid over the mold being essential.

He also stressed: (1) the importance of early grafting—even at the risk of re-contraction or partial failure—to provide covering for an exposed cornea and avoidance of ulceration and opacity formation; (2) the need to remember the bearing of other scarred areas of the face on the eyelids—release of scarring of the cheek or forehead regions often being needed to overcome drag on the eyelids; and (3) the importance of diagnosing the extent and type of loss.

Mr. Frederick Ridley spoke on the protection of the eye. His observations were

based upon the experience of a Maxillo-Facial Unit, where more than 100 cases of burns so severe as to require lid grafting had been treated. In summarizing, he stated that no coagulants should be used in the treatment of the eyelids; the splinting effect, the difficulty of proper care of the eye, the discomfort, and the fact that nothing is gained by waterproofing such a minute area are strong contraindications. Tulle gras dressings and saline packs are satisfactory. The full saline bath has a dramatic effect in alleviating blepharospasm and photophobia. Grafting of the lids should be undertaken as soon as lid retraction develops. The exposed cornea may be protected by contact lenses; delay in production, discontinuity of wearing, retention of pus, and discomfort are serious disadvantages. Lid suture is impracticable in the acute septic stage and useless in the cicatricial stage. Early cases with loss of lid tissue may be saved by sliding down a frontal skin flap and suturing over the exposed eye.

TWO CASES OF WHOLE-THICKNESS SKIN GRAFTS TO THE LOWER LID

MAJOR A. SEYMOUR PHILPS (for Sir Harold Gillies) presented two patients who had had whole-thickness skin grafts taken from behind the ear. Attention was drawn to the good color match of this skin with the surrounding area.

The first patient was badly burned about the face and hands, which resulted in marked scarring and ectropion of the lower lids of both eyes. He had both lower lids grafted in May, 1943, and a skin-grafting operation on his nose in August, 1943.

The second patient, although not injured by burning, had a marked degree of cicatricial ectropion of the right lower lid. This was grafted in August, 1943, and after two months the result appeared to be very satisfactory.

METALLIC FOREIGN BODY IN THE VITREOUS

VIOLET M. ATTENBOROUGH (for Mr. T. C. Summers) presented the case of a 37-year-old riveter who was first seen in March, 1943. He gave a history of having received an injury to the right eye one year ago while riveting duralumin. Vision in the right eye was 6/9, in the left eye 6/6. A large foreign body could be seen projecting into the vitreous. This proved to be nonmagnetic. The eye was quiet. In September the patient complained that vision in his right eye was failing; it was reduced to 6/24. The vitreous was hazy and there were metallic deposits on the surface of and in the lens capsule. There was a greenish discoloration throughout the entire lens. The left eye was unaffected.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

November 1, 1943

DR. SIGMUND AGATSTON, *chairman*

TOPICAL DIAGNOSIS OF HOMONYMOUS HEMIANOPIA

DR. ALFRED KESTENBAUM subdivides, for diagnostic purposes, the optic pathway behind the chiasm into six sections: (I) optic tract; (II) external geniculate body; (III) anterior third of the optic radiation near the internal capsule; (IV) and (V) middle and posterior thirds of the radiation in the white substance of the temporal, parietal, and later occipital lobes; and (VI) visual cortex.

The following signs are looked for:

1. Wernicke's hemianopic pupil reaction indicates a lesion in section I but it appears very rarely.

2. Atrophy of the discs, more severe on the side of the hemianopia, develops in lesions of sections I and II, but not be-

fore several months and is, therefore, not available in recent cases.

3. Optokinetic-nystagmus test. Rotation of a striped drum normally causes nystagmus. In certain cases of homonymous hemianopia this nystagmus is absent or weaker on the side of the hemianopia. This sign is significant only if there is a definite, large difference in the nystagmus of the two sides. In 41 cases in which the site of the lesion was verified (autopsy, biopsy, and so forth) the sign was positive 22 times. The radiation was always involved, twice in the temporal lobe, 16 times in the parietal lobe, and 4 times in the temporo-occipital region; that is, always section IV or V. The sign was negative 19 times and in all but one the optic radiation was not involved. Disturbance of optokinetic nystagmus on the side of the hemianopia indicates, therefore, section IV or V.

4. In certain cases of homonymous hemianopia, the eyes follow a moving object with a normal smooth movement to all sides except the one *opposite* to the hemianopia. Here the movement is made up of a series of jerks or cogwheel movements. Among 33 cases this sign was found 9 times, in all of which the parietal lobe was involved. The sign, therefore, indicates section IV.

5. In homonymous hemianopia the visual fields are sometimes very incongruent apart from the temporal crescent. Only definite incongruence can be regarded as significant. In 31 cases it was found 10 times. The lesion involved the optic tract and central ganglia 4 times, and the visual cortex 5 times. Incongruity, therefore, indicates a focus in sections I, II, or VI, the optic radiations not being involved.

6. Macular sparing of less than 3 degrees was found occasionally in any location. Macular sparing of more than 3 degrees was present in 6 of 26 cases. In

all the focus was in the occipital lobe or cortex, that is, section V or VI.

The presence or absence of these six signs allows localization of the seat of the lesion by purely ophthalmologic tests.

Discussion. Inquiry as to the significance of the Behr pupil was made. It was pointed out that a brain tumor is a complicated structure, not naturally circular and with swelling and disturbed circulation about it, all of which may make clinical diagnosis unreliable and calling for encephalography and ventriculography.

Dr. Kestenbaum stated that Behr's sign, a wider pupil on the side of the homonymous hemianopia, is infrequent. The schematic system he presented is an indication of the localization, the final diagnosis is up to the neurologist.

UNUSUAL NEURO-OPHTHALMOLOGIC CASE PRESENTATIONS

DR. PHILIP S. GOODHART presented and fully explained a motion-picture film, demonstrating unusual ophthalmologic conditions with pathologic changes in the central nervous system.

A *Marcus-Gunn phenomenon* was demonstrated in a girl, aged 13 years. She showed abnormal associated movements of the right upper lid synchronous with movements of the lower jaw.

Skew deviation. A nine-year-old boy was shown; he was later operated on and a large cerebellar neoplasm was removed. The patient was shown previous to operation and the skew deviation demonstrated; upon outer gaze the homolateral eye turned downward and outward, the other eye upward and inward. Skew deviation was due to brain-stem lesion.

Types of nystagmus. Three patients with multiple sclerosis demonstrating different types of nystagmus were shown. The pathology was doubtless in nerve fibers or centers of association between

the longitudinal fasciculus and respective centers controlling eye movements.

Weber's syndrome. A man, aged 50 years, was presented. He had paralysis of the third cranial nerve with contralateral hemiplegia; vascular lesion of the basis pedunculi.

Duane syndrome. Two patients were shown in which unilateral and bilateral Duane syndrome, respectively, were demonstrated. Both were neurologic cases and the finding of the Duane syndrome was incidental, the latter due to fibrosis of the levator oculi superioris and of the external rectus. As a result there is widening of the palpebral fissure as the eye turns outward and narrowing as it turns inward; there is also limitation of external gaze in the affected eye.

Postencephalitis syndrome. There is inability to open voluntarily the closed eyes without throwing the head far backward.

Congenital absence of posterior orbital wall with resulting pulsating exophthalmos in a case of von Recklinghausen's neurofibromatosis was demonstrated.

Pathologic specimens were also presented.

OCULAR FINDINGS IN 1,200 CASES OF HEAD INJURY

DR. NATHAN SAVITSKY personally studied 1,200 cases over a period of 13 years. All the injured were studied three weeks or later after the initial trauma. No acute cases were included in this series.

He encountered 112 organic ocular findings attributable to the head trauma in 109 different patients. The commonest finding was discomfort with conjugate gaze which was seen in 56 patients (4.6 percent). Control studies of the incidence of discomfort with conjugate gaze have been completed with Dr. M. Madonick. Such discomfort was found in only 1 of 2,000 cases diagnosed as psychoneuroses

and in 4 of 10,000 draftees. The other organic ocular findings were:

1. Unilateral optic atrophy—2 cases.
2. Divergence paralysis—5 cases.
3. Isolated ocular palsies—9 cases; of these 5 involved the superior rectus and 3 had ptosis.
4. Bilateral sixth-nerve palsy—2 cases.
5. Pupillary changes were noted in 11 cases as follows: unilateral dilation—7; bilateral dilation—2; paradoxical pupil—1; and irregular fixed pupils—1.
6. Enophthalmos—2 cases.
7. Limitation of upward gaze—1 case.
8. Visual-field disturbance—8 cases; of these 6 were homonymous hemianopia, 1 was a ring scotoma, and 1 central scotoma.
9. Bilateral papilledema—2 cases.
10. Nystagmus—3 cases; 2 rotary and 1 lateral.
11. Alexia—1 case.

Attention was called especially to the frequency of divergence paralysis due to an injury to an hypothetical divergence center in the brain stem. Nystagmus is a rare sequel to head injury, and its presence should make one particularly careful about ruling out concomitant disease. In 12 of the isolated ocular palsies there was no evidence of injury to the orbit or eye. Indirect traumatic palsies of the ocular muscles can take place. In neither case of optic atrophy was there direct injury to the eye or orbit.

In 15 cases in this series the ocular findings were due to diseases unrelated to the trauma. Careful neurologic examination and accurate anamneses are extremely important. In 6 of these cases there was optic atrophy unrelated to the trauma. In 218 cases (16 percent) there was undoubted evidence of functional superimposition in the nature of conversion hysteria. Of these 186 had a functional hemisensory syndrome with blurred vision or diminished perception of bright-

ness on the same side. Contraction of the visual field on that side was inconstant. In addition there were 2 cases with markedly contracted fields, 3 with monocular diplopia, and 1 case of spasm of convergence.

The most common subjective complaints were transitory obscuration of vision with change of position, blurring of the printed page after reading for a short period of time, and spots before the eyes. Sensations of heaviness, tightness, and burning in the eyes were frequently reported in these cases, especially in those who showed other evidence of psychogenic superimposition.

Discussion. Dr. A. Kestenbaum agreed with Dr. Savitsky regarding hysteria and cited a case of encephalitis simulating hysteria; the patient had retinospasm every Monday, Wednesday, and Friday.

Dr. M. Davidson said he has frequently found miosis on the side of scalp laceration in cases of head injury. Optic atrophy, appearing after head injury, when it had not been noted on examination in the hospital for the head injury, must be assumed not to have been present before. He was not convinced that divergence paralysis, seen a few times, was organic in nature. Early presbyopia is of frequent occurrence, and glasses are immediately recommended. Opticochiasmatic arachnoiditis, often not properly diagnosed preoperatively, is being discovered at operation following head injury.

Dr. Savitsky, in conclusion, pointed out that his series included the most severe as well as mild cases of head injury and that the severity made no difference in the optic sequelae as far as he could see. He has seen cases of optic neuritis—that is, inflammation of the nerve head—following concussion. There is such a thing as traumatic hydroencephalitis with papilledema. He has not found anisocoria with scalp lacerations following

head injuries although he has looked for it.

Leon H. Ehrlich,
Secretary.

CHICAGO OPHTHALMOLOGICAL SOCIETY

November 15, 1943

DR. VERNON M. LEECH, *president*

(Presented by the Department of
Ophthalmology, University of
Chicago)

CHRONIC NONINFLAMMATORY GLAUCOMA

DR. THOMAS D. ALLEN, C. O. P., a man, aged 62 years, was first seen 16 years ago with Dr. Wilder. At that time the vision was R.E. 20/40, corrected to 20/30+; L.E. 20/30+, corrected to 20/20+. The pupil of the right eye measured 4 mm. and the left 3 mm. No medication had been used for several days. The tension was R.E. 60 mm. Hg, L.E. 27 mm. Hg (Schiötz). The optic disc of the right eye was sharply outlined and glaucomatous cupping, 4 diopters deep, extended to the periphery. The vessels bent sharply at the disc margin and there was a glaucomatous halo. The optic disc of the left eye had a large physiologic cup which sloped temporally and extended nearly to the disc edge. The visual field of the right eye was considerably contracted and indented almost like a swastika; that of the left eye was fairly good.

The patient was advised to use 1-percent pilocarpine six times a day and to adopt general hygienic measures. He was seen at intervals, and finally a trephining operation was performed on the right eye on January 30, 1928. No surgical difficulties were encountered, but atropine

was instilled in both eyes on the first postoperative day. This caused the tension to rise to 60 mm. in the left eye, but it was reduced to 20 mm. by immediate and vigorous measures. Postoperative vision with correction was R.E. 20/20-; L.E. 20/15. The tension, R.E., varied between 10 and 22 mm., an average of about 15 mm. The central vision gradually decreased and the visual fields contracted. Then, in 1941, a secondary infection robbed the patient of all vision in this eye. This infection was conjunctivitis, corneal ulcer, and endophthalmitis which was not controlled by four weeks' treatment with small doses of sulfanilamide. Cure was effected, however, in two or three days, when the dosage of sulfanilamide was greatly increased. Hemolytic *Staphylococcus albus* was cultured from the ulcer. The tension, R.E., which was high at the time of the infection, subsided to normal. Since that time there have been no further complications.

The tension of the left eye remained low on miotics for over two years. In July, 1930, the use of pilocarpine had been stopped for 24 hours, the tension was found to be 66 mm., although the vision and fields were good. An iridencleisis was performed under a thick conjunctival flap, the pupillary edge being cut and the iris tucked in the corner of an oblique conjunctival-limbus incision. The patient recovered very quickly from the operation. The tension since that time has never risen above 20 mm. and has usually been 10 or 12 mm. Vision with correction, more than 13 years after operation, is 20/20+. The visual field has remained normal.

This case was shown as an illustration of iris-inclusion operations. There remained at this time a very circumscribed, somewhat glassy bleb over the trephined area of the right eye and slight conjunctival edema in the left eye. The trephining

was done comparatively later in the course of the disease than was the iridencleisis. It might be unfair to conclude that the iris-inclusion operation is better than the trephining from this one case; one might get the impression, however, that the inclusion operation is less hazardous than the trephining.

MELANOSIS

DR. THOMAS D. ALLEN presented L. B. C., a woman, aged 64 years, who was first seen with Dr. Wilder nearly 24 years ago. At that time she had a rather darkly pigmented superficial lesion at the nasal side of the right eyeball, about 12 by 12 mm., extending about 2 mm. onto the cornea. This had grown from a small spot first noticed when she was four years old. During the year 1919 it began to show some activity. After several consultations she was given 45 radium treatments of 50 to 100 mg. each, because she refused to have the eye removed. At the end of 15 months the growth seemed to have almost entirely disappeared. Several months later it began to spread again in the upper and lower fornices. After a course of 40 more radium treatments it became apparent that the growth was progressing.

Dr. William Brown then gave nine treatments with heavy doses of radium, a total of 110 mg. As a result the lesion completely disappeared in about 6 months and had not reappeared after 21 years. The patient had no cataract, although there was a very slight peripheral cortical change in each lens. Vision in each eye was 20/20+ with correction. The patient was in excellent health.

This case, which was reported by Dr. Wilder in 1923, before the American Ophthalmological Society, was shown to call attention to the following facts: (1) The lens had not suffered; (2) the patient remained well and had normal vi-

sion; and (3) there was no recurrence of the tumor.

BILATERAL NERVE ATROPHY AND NYSTAGMUS

DR. R. J. MADI. A. C., a girl, aged 16 years, was first seen in the eye clinic at Central Free Dispensary in June, 1938. The parents stated that oscillating movements of each eye were first noted when she was six years old and that her vision seemed poor.

On examination the vision, R.E., was 0.2-1; L.E., 0.1. A horizontal jerky nystagmus of varying amplitude was present, increasing in lateral gaze to the right or left. The palpebral conjunctiva of each eye was mildly injected. The extraocular muscles, tactile tension, lids, cornea, and anterior chamber were normal in each eye. The irides were light blue. The media were clear. The disc of the left eye was a marked typus inversus with a narrow inferior conus; that of the right eye was a moderate typus inversus. Each disc showed a grayish pallor.

She had been refracted each year and the best vision obtainable with correction was 0.4-1 in each eye. She progressed satisfactorily in sight-saving classes.

BILATERAL POSTTRAUMATIC OPTIC-NERVE ATROPHY

DR. CHARLES A. LEARSY. The patient, a 35-year-old man, was first seen at Central Free Dispensary of Presbyterian Hospital on October 18, 1943. He had had a head injury on February 10, 1943, and was unconscious for about two weeks. The right eye was blind on discharge from the hospital. Since June, 1943, some vision gradually returned. At first examination vision, R.E., was 4/200; L.E., 0.8-2. Each disc, particularly that of the right eye, was pale with fairly definite borders but there was some connective tissue in the central ex-

cavation and white connective-tissue sheathing on the central vessels. The peripheral field of the right eye was reduced to a wedge-shaped area in the inferonasal quadrant; that of the left eye showed only slight temporal constriction.

X-ray examination on October 14, 1943, showed an "old fracture through the roof of the right orbit, with slight separation of fragments." The optic atrophy was considered probably secondary to an initial papilledema which followed increased intracranial pressure and some additional direct involvement of the right optic nerve.

FIBROPLASIA OF RETINA

DR. R. C. GAMBLE, J. D., a six-year-old girl, was first seen at Children's Memorial Hospital five years ago. She was born prematurely, her birth weight being 25 ounces. The right eye was small, the anterior chamber shallow, and the pupil small. The lens was clear but behind it was a gray mass. No red reflex was obtained. The left eye was similar to the right except that the membrane behind the lens was on the nasal side only. A red reflex could be seen on the temporal side and in this area an arborizing group of blood vessels could be seen. A cataract then formed in this eye so that the membrane and vessels could not be seen.

This bilateral type of retinal fibroplasia is found in premature children. There is a unilateral type of persistent posterior fibrovascular sheath which is found in children born at term.

BILATERAL RETINOBLASTOMA

DR. ARTHUR J. STRICH. The patient, a 2½-year-old girl was admitted to Children's Memorial Hospital because of what appeared to be a severe inflammatory condition of the right eye, blepharospasm, lacrimation, and pain. The cornea was yellow and opaque. The tension ap-

peared to be normal. The fundus of the left eye, well seen through the clear media, was dominated by large gray choroidal patches traversed by undisturbed retinal blood vessels. A diagnosis of endophthalmitis in the right eye and exudative choroiditis in the left eye appeared rational except for the clearness of the media of the left eye. As the lesions of the choroid of the left eye gained thickness and the discomfort caused by the right eye did not subside, the latter was enucleated. A retinoblastoma with an unusual amount of calcification was found. To this Dr. Gamble attributed the inflammatory character of the pathologic condition, as the areas of calcification were imbedded in large leukocytic infiltrates. The child received radiation therapy.

TWO CASES OF ENDOPHTHALMIA

DR. ARTHUR J. STRICH. Each of two babies had had an endophthalmitis in recent months, and each received energetic atropinization and sulfa therapy.

The first case followed a pustular dermatitis. Culture from the skin lesions revealed *Staphylococcus aureus* and *albus*. Treatment was started the sixth day after the eye became red. The outcome was retinal detachment and atrophía bulbi.

In the second case the endophthalmitis developed in the course of a meningococcal meningitis; treatment was started on the third day after the eye became red. A slight discoloration of the iris and a few spots on the anterior surface of the lens were the only remaining findings.

TAPETO-RETINAL DEGENERATION

DR. ARTHUR J. STRICH. The patient, a two-year-old boy, was brought to the Children's Memorial Hospital four months ago because of poor vision and nystagmus. He was typical of a small group of children with these symptoms,

who were under observation. The ophthalmoscopic findings showed a pigmentary change, a large central area of very fine depigmentation and dustlike pigmentation. The discs were pale, and the blood vessels very thin. The macular regions and the periphery did not show anything of significance. There seemed to be some mental retardation. The only significant finding in the family history so far was that the mother had what was termed a "menopausal psychosis."

This was not the ordinary form of retinitis pigmentosa, in which the changes are in the periphery and not in the central region. It was not so-called central pigmentary degeneration because there the pigment, according to Duke-Elder, appears as "either spiderlike clumps or scattered black dots forming an island around the macula," whereas in these cases the pigment appeared as an extremely fine dust. It was not the infantile form of amaurotic familial idiocy in which, according to Spielmeyer and Vogt, the pigmentation appears as a well-defined patch in the macula. It may be that this form represents a distinct form of what Leber termed "tapeto-retinal degeneration."

DISSEMINATED CHORIORETINITIS, RIGHT EYE

DR. JUSTIN M. DONEGAN. A woman, aged 38 years, was first seen in the Central Free Dispensary on November 4, 1943. Three months previously vision in the right eye failed overnight to the degree that she could not distinguish faces at 10 feet. There was no associated pain nor were there inflammatory symptoms. The vision of the left eye had always been poor. The patient was under treatment in another clinic for congenital syphilis.

Examination showed that the corrected vision was R.E. 0.4+1; L.E. 6/200. The ocular media were clear; the disc in the

right eye was normal; that of the left eye was a *typus inversus*. Just temporal to the fovea of the right eye was a slightly raised greenish-black pigmented mound, 1 P.D. in size, and near its nasal edge was a small bright dot of hemorrhage. The macular region of the left eye showed a black-and-white roughly horizontal oval area of old healed chorioretinitis measuring 2.5 by 1.5 P.D. Immediately adjacent to the fixation point nasally in each central field was a roughly oval scotoma of 7 by 5 degrees as determined by visual-field studies of the right eye, and 10 by 8 degrees in the left field. The blind spot shown by the left eye was irregularly enlarged to four times its normal size, and the peripheral field of the left eye presented a generalized constriction.

CYANOSIS OF THE RETINA

DR. ROY O. RISER. S. X., a nine-year-old boy, had been under observation for several years at Children's Memorial Hospital because of a probably congenital heart disease with a compensatory polycythemia. He did, however, present some findings of polycythemia vera, according to the department of hematology. He had the clubbed fingers characteristic of a congenital heart disease. The blood showed 7,030,000 erythrocytes per cubic mm. and 115 percent hemoglobin determination. Cyanosis of the face, lips, hands, and so forth, accompanied the flushing of the bulbar conjunctiva, and the typical retinal picture of very large dark veins, enlarged arteries of slightly lighter hue, and flushing of the discs and retina generally. Kodachrome fundus photographs accompanied the presentation.

CORNEAL LEUKOMA—CONGENITAL PERSISTENT PUPILLARY MEMBRANE

DR. ROY O. RISER. J. L., a five-year-old Nègro boy, had red eyes when two

months old, the left worse than the right. He had received treatment for one month in the rural part of Arkansas.

The right eye was normal. The patient had a convergent strabismus of the left eye of 40 degrees. There was a central dense deep corneal leukoma, 2.5 mm. in diameter, obscuring a golden-brown plaque, 2 mm. in diameter in the pupil. Running from this plaque to the collar-ette of the iris at the 2-o'clock and the 10-o'clock positions were golden-brown threads. A red reflex was barely discernible in the left eye.

Kahn and tuberculin tests gave negative results. Physical findings were normal. The slitlamp examination showed no signs of old interstitial keratitis. In addition to the aforescribed pathologic changes the patient had an amblyopia. No treatment was advised.

SCIENTIFIC PROGRAM

HISTORY AND DEVELOPMENT OF THE IRIS-INCLUSION OPERATIONS

DR. THOMAS D. ALLEN presented a paper on this subject which has been published in this Journal (September, 1944).

Discussion. Dr. Sanford Gifford said that he had performed the operation frequently since 1927, when he reported a series of cases before the American Academy of Ophthalmology and Otolaryngology, and believes it to be one of the two most valuable procedures at their disposal in chronic simple glaucoma. The other procedures to be compared with it are, of course, Elliot's corneoscleral trephining and the sclerecto-iridectomy of Lagrange. In this hierarchy he felt inclined to place trephining first, iridencleisis second, and sclerecto-iridectomy third, although he recognized that many good surgeons, especially in France, prefer the last named and obtain results with it comparable to those with trephining.

A comparison of trephining and iridencleisis might be made as follows:

Advantages of trephining: (1) Great effectiveness in reducing tension, especially in the higher brackets, (2) round central pupil, and (3) little need for after care except the use of a mild antiseptic for life.

Disadvantages of trephining: (1) Greater technical skill and experience required. (2) More danger of certain complications, such as (a) wounding the lens capsule; (b) late infection; (c) prolonged hypotony; and (d) loss of central field.

Advantages of iridencleisis: (1) Simplicity of execution; it is undoubtedly the easiest effective filtering operation for the surgeon of moderate experience. (2) Less danger of complications: (a) wounding the lens capsule is exceedingly rare; (b) late infections are exceedingly rare; (c) prolonged hypotony is rare, the chamber being filled usually after 48 hours; (d) probably because of this fact, loss of the central field is rare. (3) Iridencleisis is generally effective in reducing tension to normal limits.

Disadvantages of iridencleisis: (1) It is probably less effective in reducing tension in the higher brackets. (2) Hence, more after care is required, including miotics and massage in some cases and occasionally a secondary operation. (3) The pupil is not round and may be slightly high. A really high pupil should never occur if Holth's simple technique is carefully followed, whereas it always occurs following the iridotaxis of Borthen.

From this outline may be deduced the reasons for a set of indications for the two operations which have been gradually reached. As indications for trephining he said he considers the following conditions:

1. Cases of chronic simple glaucoma in which the tension cannot be reduced be-

low 40 mm. Hg (Schiötz) by miotics, provided the field is not cut down close to the fixation point.

2. Cases of very low-tension glaucoma in which the field is being lost while tension is seldom above 25 mm. Hg (Schiötz). This seems like a paradox, yet he said he believes that it is rational here to perform an operation which will reduce tension to the lowest degree possible.

As indications for iridencleisis the following conditions are usually considered valid:

1. Cases of chronic simple glaucoma in which the tension can be kept between 25 and 44 mm. Hg (Schiötz) by miotics.

2. Cases in which the tension is higher, but the field is cut down close to the fixation point.

3. Cases of hydrophthalmos. His preference for iridencleisis in this condition has come from a series of favorable results when the operation was performed early, and is supported by reports of cases in which trephining allowed the greatly stretched zonula to rupture during trephining, allowing fluid vitreous to escape and resulting in phthisis bulbi. He said that so far as he knew this has never occurred after iridencleisis.

As to technique, he believed the best procedure to be the simple iridencleisis of Holth, in which one meridional cut is made through the iris sphincter and the portion of iris next to this cut is turned out through the scleral incision and left beneath the flap. He said that everyone likes to make modifications in procedure, but the only ones he advocates in this operation are the use of the Foster Moore so-called water-tight suture and fixation forceps on the superior rectus. After injection of 4-percent novocaine, H. Gifford's forceps are placed on the superior rectus tendon through the intact conjunctiva as far back as possible, so as to give room for a very large conjunctival

flap. A straight horizontal cut is made in the conjunctiva just in front of the forceps, long enough to extend past the limbus on each side. Dissection of the flap is made close to the sclera, but not so close as to wound the scleral vessels. It extends just to the limbus and is undermined to expose the whole upper limbus. While an assistant holds the flap down, a very sharp keratome is inserted 1 mm. from the limbus far enough to make an incision 5 mm. long. The surgeon holds the fixation forceps and cuts with the keratome directly against his fixation. The point of the keratome is raised as it is withdrawn and the iris usually follows it into the wound. It is grasped with iris forceps and withdrawn far enough so that the sphincter border is visible. This is cut with iris scissors and the portion held in the iris forceps is turned out under the flap with the pigmented side upward. It is not manipulated at all except for this maneuver. A few pats with a spatula on the cornea usually suffices to replace the remaining iris pillar and it is seldom necessary to introduce the spatula into the anterior chamber. A running conjunctival suture is then used to close the conjunctival incision with about 8 to 10 bites, enough to close the incision tightly, leaving an untied portion of suture at each end. Then, and not until then, is the fixation forceps released.

The suture is removed, after six days, from both ends, after one of the loops near the middle has been cut. Use of the water-tight suture seems to favor early refilling of the anterior chamber and early development of a filtering bleb. In the first 21 cases which, he said, he reported, there were no cases of delayed filling of the anterior chamber. There have been a few since that time, among several hundred operations, but they are certainly more rare than after trephining or after iridencleisis without the suture. This su-

ture was designed for use in corneoscleral trephining and is equally useful in that operation. The same may be said of fixation on the superior rectus, which ensures a large flap, perfect control of the eye during operation, and an opportunity for accurate closure of the conjunctival incision.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

SECTION ON OPHTHALMOLOGY

November 18, 1943

DR. ALFRED COWAN, *chairman*

DIABETIC CATARACT

DR. GEORGE J. DUBLIN, by invitation, stated that diabetic cataract is a distinct clinical entity. Rollo is the first to be credited with speaking of cataract as a complication of diabetes. Generally speaking, it is subdivided into two types. The first type of the so-called diabetic cataract is found in the adult in association with diabetes mellitus. This type of cataract is a common finding, and is observed repeatedly in association with diabetes. It is similar in appearance to the senile cataract including the cuneiform, saucer-shaped, and nuclear types. Actually there is no differentiation, and it is impossible by any known method of observation to tell them apart, even by slitlamp microscopy. In both the senile cataract and the type of lens opacity found in the adult with diabetes, slitlamp microscopy reveals vacuoles, fluid clefts, and lamellar separation in the cortex together with various opacities in the lens. Gradle, in a series of 76 cases of diabetes, found lens changes in 41, with a blood sugar averaging 298.7 mg. per 100 c.c. of blood.

The second type of lens opacity is found in the diabetic under 35 years of age. This is the true diabetic cataract and it is this type that is referred to under the classification of diabetic cataract. It has been considered a rare condition. O'Brien, Mullsbury, and Allen reported a series of diabetic cataracts in patients under 35 years of age amounting to 16 percent. In 1942 O'Brien and Allen reported another series of cases in which they found 36 patients with cataracts out of a number of 260 cases under 21 years of age (13.8 percent). True diabetic cataract may assume one of the following pictures, but they all have the same characteristic in that the opacities are all subcapsular in location immediately adjacent to the subcapsular line. The common picture is the snow-flake type of O'Brien, subcapsular in location, whitish in color, and irregular in form and size and truly resembling snow flakes. The second type is the arrangement of the opacities as irregular large and small plaques together with fine dust-like opacities having a dirty-brown color, subcapsular in location, and strongly resembling the senile cuneiform type of cataract. The third type is the bluish-white opacity in which the lens may become completely opaque and swollen in one to three weeks (hydrops capsulae lentis). This is the malignant form of diabetic cataract. According to O'Brien and Allen lens opacities in young diabetics occur invariably in those whose diabetes has been poorly controlled or uncontrolled for several months. After standardization of the diabetes, these opacities may progress slightly but after six months of control the lens opacities generally remain stationary.

He presented the case of Mrs. M. R., a 22-year-old white woman. She was admitted to the Metabolic Department of Philadelphia General Hospital. She had

had diabetes for 10 years. She developed a sore throat six days prior to admission. A diagnosis of cervical adenitis and acute bronchitis was made. The main pertinent finding was that the blood sugar ranged from 245 mg. to 356 mg. per 100 c.c. of blood on the day of admission.

She had been receiving 60 units of insulin for an uncontrolled and unstabilized diabetes. Routine examination of the eyes was negative externally; eye-grounds were normal. Both lenses showed irregular dirty-brown opacities as large and small plaques involving the anterior and posterior subcapsular zones in both eyes. Some of these opacities were pointed, resembling the cuneiform type of senile cataract. There was a small clear area of cortex between the opacity and the subcapsular line. The remaining lens was entirely clear. The vision was 6/60 in each eye, corrected with glasses to 6/12 in each eye.

Discussion. Dr. Alfred Cowan said that O'Brien and his associates divide what they call diabetic cataract into two groups. The type that Dr. Dublin reported is in the group that includes those that resemble the senile disciform cataract. At first the opacity in this case would appear to be just in front of the posterior capsule, but with the narrow beam of the slitlamp it is seen to lie just behind the face of the adult nucleus, leaving a narrow space behind the posterior capsule. The space is so narrow, because at the age of this patient, 22 years, the cortex is very small. Usually opacities in the lens occur in the youngest zone, but they lie deep, down to the last surface of discontinuity.

In the case reported by Dr. Dublin, the opacity was disciform, yellowish gray, and similar in every respect to the ordinary senile type.

Dr. James S. Shipman said that in his experience diabetic cataract had been

very rare. A patient under his observation for the past 15 years finally went blind, not from cataracts, but from diabetic retinopathy which was first to appear in his case and was quite gradual but definite. At present he is blind from the retinopathy, cataracts, and secondary glaucoma superimposed. So, diabetes does take its toll, and cataract is a definite complication. He said he believed that the criteria given by Dr. Dublin are as good as any; namely, the age of the patient, the history of diabetes in the presence of a high blood sugar, and the position of the opacities outside the embryonic nucleus.

Dr. H. Maxwell Langdon said he thought that Dr. Dublin was accurate in saying that it is difficult to tell diabetic cataracts from lens changes due to other causes. If the patient has a cataract and a high blood sugar with a spill-over into the urine, it is probable that the cataract is diabetic in origin; but it is doubtful whether in all such cases the cause of the cataract is the diabetes.

Many cataracts in young people remain unexplained. He said he had two such cases. The first patient was a 26-year-old woman with bilateral cataracts, who has been under observation for over five years. She had a careful physical examination with special reference to metabolic tests, and it was found that she had definite signs of hyperthyroidism. The thyroid was then operated upon. He said he thought that possibly some interference with the parathyroid caused the lenticular changes. There were no signs of diabetic changes whatsoever. The cataracts gradually advanced, and the vision of one eye was reduced to 2/60, so that the patient will undoubtedly require operation.

The second patient, a 37-year-old man, suddenly discovered that the vision of one eye was very defective. He was seen

the following day and the vision of this eye was limited to light perception. Examination revealed a practically mature cataract. The other eye was normal in all respects. He had been examined one year ago and his eyes were normal. A careful physical examination showed nothing to indicate such a condition. If either of these patients had diabetes, undoubtedly it would have been said that these were diabetic cataracts.

There are many elderly people who have ordinary senile changes in the lens, who also have an increase in the blood sugar and some sugar in the urine. These cases are usually classed as diabetic cataracts, and they may be; but it seems open to question whether or not the condition should be called diabetic cataract in a person with diabetes.

He said that he thought in the case presented by Dr. Dublin the cataract undoubtedly is due to the diabetic condition.

Dr. I. S. Tassman said that it seems there are other factors involved in the occurrence of cataract among these patients. The blood-sugar concentration, at any one time, in patients with diabetes is probably not the determining factor in the production of cataracts. Some diabetics have a high blood sugar and no cataract nor retinopathy. In others with a comparatively low blood sugar, cataract may be found alone or in association with retinopathy. These metabolic disturbances do not affect all patients in the same way. When a young patient with diabetes develops cataract, he said that he thought it should be called a diabetic cataract. However, there are certain unknown factors present, in addition to the blood sugar concentration, which are probably causative factors in the production of the ocular condition in these cases.

Dr. Solomon S. Brav said that he had

seen in consultation with his son, a 14-year-old child who had diabetes. There were no signs of retinal pathology or diabetic retinopathy, but the vision was reduced to 2/200 because of the lens opacities. It was questionable whether or not the condition was congenital or diabetic. The child was operated on about one year later. The cataract in each eye was extracted and the resultant vision was 20/30 in each eye.

Dr. George Dublin, in closing, said that diabetic cataract in the young person should not present too great a problem in differentiating it from a congenital cataract. The various layers of the lens develop at certain periods of life, and congenital opacities of these layers have a typical location and appearance. For instance, if a congenital opacity is limited to the embryonal layer, it is evident that the opacity occurred at some time in the first three months of uterine life. If the opacity is in the fetal nucleus, it occurred between the third and eighth month of fetal life; and if it was in the infantile nucleus, then it probably occurred the first month after birth. The adult nucleus is developed about the age of 10 years and upwards, so, an opacity of that zone would indicate involvement at the age of puberty.

Congenital cataract, unless it is completely opaque with obliteration of all layers of the lens, would be comparatively easy to diagnose. The history of diabetes, and its rapid onset would be a big help in differentiation. It was mentioned before that there is a malignant type of diabetic cataract called "hydrops capsulae lentis." This is the bluish-white cataract that is present together with marked edema. He stated that this is, in his opinion, about the only type that might be confused with a total congenital cataract. The other types of diabetic cataracts progress slowly and do not mature with-

in several weeks, as has been stated at times.

In the case presented here the cataract had been present for about one year. A previous eye examination two years ago failed to reveal any lens opacity. O'Brien and Allen have brought out some interesting facts and figures. They claim that diabetics who have not been standardized are the ones that develop these cataracts. O'Brien states that if a period of six months or more elapses without good control, poor control, or without any control at all, the opacity is then likely to develop, and he further claims that if the case is under complete control or has been standardized for approximately six months, then rarely is there any further development in the cataract. After they reach a certain stage, they remain stationary.

Diabetic cataract is very similar, and may be confused with other endocrine cataracts, such as parathyroid and tetany cataracts. In this the location is very similar, and the opacities are in the deep portion of the cortex, but frequently they have a blue and green color. Other types of cataracts due to glandular disturbances are cretinism, myotonia, atrophica, and Mongolian idiocy. All these opacities are very similar in location and appearance, and without a history and physical examination, are extremely difficult to differentiate from diabetic cataract.

EPIDEMIC KERATOCONJUNCTIVITIS

DR. H. MAXWELL LANGDON, DR. VAN M. ELLIS, and DR. ROBERT D. MULBERGER said that epidemic keratoconjunctivitis was first reported by Hogan and Crawford in 1942 (*Amer. Jour. Ophth.*, September, 1942). It is characterized by congestion and swelling of the conjunctiva and lids; at times, a false membrane, more likely to be on the conjunctiva of the lower

lid; frequent enlargement of the preauricular glands; and round or ovoid dots on the cornea just below Bowman's membrane which are highly refractile and may break down and show some slight staining.

Cases in the eastern part of the country have not differed from this description. The course of the condition is very irregular and there is no specific treatment although injection with convalescent blood has not been tried. In many cases there was a preëxistent slight injury or inflammation of the eye from a week or two weeks previously. Cultures show indifferent growth—usually diphtheroids or *Staphylococcus albus*.

Major Murray Sanders (MC) in 1942 reported the finding of a virus which produced encephalitis in mice, and after injection into a healthy man, who acted as a volunteer, produced a conjunctivitis; corneal complications, however, were not mentioned.

The corneal dots may entirely disappear or leave faint gray areas behind them. The cases they saw had complete recovery of vision to normal or better, although in one case it was reduced to 5/30 during the acute phase. In none of the cases were they able to trace any definite connection with an infected case. They regarded the corneal dots as the most definite diagnostic point.

Treatment consisted mainly of boric acid and holocain solutions for the discomfort; ice compresses for the swelling; tannic acid or silver nitrate for the catarrh of the conjunctiva; and in the later stages 10-percent boric-acid ointment for massage, which, they felt, aided in the clearing of the cornea.

They had 45 patients with corneal complications; 31 male, and 14 female. Both eyes were involved in 7 patients; the right eye in 23; and the left eye in 15.

Some of the most severe cases were

binocular, and it was felt that these patients were particularly susceptible. There were about 25 other cases which represented the conjunctival type of the condition, and in which there were no corneal complications.

Discussion. Dr. Edmund B. Spaeth said that Dr. Brealey presented an analysis of some 300 cases of this form of keratoconjunctivitis at the Academy meeting, in 1943. He emphasized the fact that when these patients recover, they usually continue their recovery. Also, their symptomatology may disappear, while they still have clinical signs of disease of the infiltrated cornea. For that reason the patient presented here is interesting.

This patient reported 10 weeks ago with a severe unilateral keratoconjunctivitis of the epidemic type. It was so severe that she had to be hospitalized. Ten days later she was out of the hospital, and 10 days afterwards, she returned to work. Six weeks later, she returned with the lids of the right eye swollen with edema, lacrimation, photophobia, and a sticky discharge. The condition was not a recurrence because she had not recovered, although she had apparently recovered for all clinical purposes, but six weeks later she had symptoms almost as severe as the first time.

He stated that, in his opinion, the best treatment is cold compresses in the early stages, heat later, adrenalin, and enough holocaine to keep the patient comfortable. Sulfathiazole proved of no value whatsoever. As a matter of fact, it seemed to cause irritation. Specific serum, if administered very early in the condition, relieves the symptoms to a marked degree, and apparently shortens the course of the disease.

Dr. A. G. Fewell said that during the keratoconjunctivitis epidemic he saw

about 12 cases. His experience was the same as that of Dr. Langdon in that no two cases were in the same family. They came from scattered areas and all had glandular involvement. Mucopurulent secretion was not present in any of his cases, although there was considerable tearing and some ropery secretion. The majority of his cases were bilateral, and all but one had some involvement of the cornea. The one patient who had no involvement of the cornea was the only one who was given convalescent serum, and cure was effected within a week. The other cases were treated with holocaine and adrenalin. After the appearance of the corneal lesions, the majority of them were treated with Pregl's solution, which seemed to help clear up the corneal opacities a little more rapidly than those in which it was not used.

Dr. Solomon Brav said that in most cases there are chemosis and severe burning of the eyes. He had not seen any cases in which there was mucopurulent discharge. He stated that in his experience there has occurred a distribution of the infection in one family. It is probable in some cases that the mode of transmission is through the doctor's office.

Dr. Irving L. Pavlo said that at Wills Hospital there have been several hundred cases of this condition during the past year. There have been several waves of infection among clinic patients with glaucoma who have had their tensions taken at short intervals with the same tonometer which must have been insufficiently sterilized. Also, in the cataract wards there were several severe waves of infection, twice necessitating a quarantine. Most of the epidemiologic evidence pointed to an incubation period of 8 to 11 days, more often the latter. This was shortened in the case of the postoperative cataract extractions, in many of which

the full-blown disease appeared by the second or third postoperative dressing. It was interesting to note that none of these cases had any intraocular complications.

Dr. H. Maxwell Langdon said that for clearing up the corneal opacities a 10-percent solution of boric-acid ointment massaged on the eye and placed under the lids is beneficial.

EXTERNAL OPHTHALMOPLÉGIA

Dr. VAN M. ELLIS presented the case of a young Negro girl. She was first seen at the Presbyterian Hospital Clinic when she was 1½ years old, at which time the mother stated that both eyelids had been drooping for the past two weeks. Her case had been followed in the Clinic up to this time.

The findings when last seen were as follows: The vision of the right eye was 6/30, and of the left eye 6/12, with correction. The pupils were normal. The patient had a ptosis; complete third-, fourth-, and sixth-nerve palsies. The eyes were immobile and the right eye diverged about 20 degrees. The internal structures of both eyes were normal.

The neurologic report, other than the ocular findings already described, was negative. The pediatric consultation suggested that the condition was the result of congenital lues; however, repeated Wassermann tests had all proved negative. Palpable epitrochlear glands were present. There was, however, a definite family history of lues. Myasthenia gravis had been ruled out by therapeutic tests, prostigmine, and electrical reaction tests. Complete physical examination, including laboratory tests and spinal-fluid examination, was negative.

Hence, this was believed to be a case of external ophthalmoplegia, etiology undetermined.

Discussion. Dr. Walter I. Lillie said

that this case was very suggestive of a congenital absence of the posterior longitudinal bundle, inasmuch as there was complete paralysis of ocular rotations of both eyes but pupillary reflexes were not involved. He suggested that caloric tests be done on this patient to see if nystagmus could be produced by stimulating the semicircular canals. If nystagmus is produced, it would show that there is still function in the posterior longitudinal bundle, and the lesion would be supranuclear.

EXUDATIVE CHOROIDITIS

Dr. I. L. PAVLO (by invitation) said that a 26-year-old man was seen at Wills Hospital on November 3, 1943. He complained of blurred vision of the right eye which occurred three weeks previously, or 10 weeks after onset of a typical pneumonia that had left a residuum of hoarseness and persistent cough with much tenacious, nonfoul, mucopurulent, blood tinged sputum. Visual difficulties began after a night of severe coughing.

The right eye showed small gray keratic precipitates and aqueous flare. The lens was clear, the vitreous slightly hazy, and there was a light yellow-gray, 2½-D.D. exudate over the macula and disc, elevated 2 diopters. This area contained small hemorrhages, the veins were dilated, and perivasculitis was present. The visual field showed a 34 by 43 cm. caecentral scotoma. The vision, R.E., was ¼/60.

Examination of the left eye was completely negative and the vision was 6/6.

Two badly carious teeth were extracted. An acute maxillary sinusitis was drained, yielding frank pus which, unfortunately, was not examined bacteriologically. Ten days later the sinuses were clear.

There were rales at the base of the left lung. X-ray study showed homogeneous

haziness over the left lower lobe, with some faint mottling, thought not to be tuberculous. The heart and blood pressure were negative.

The possibility was entertained that this was a typical chronic B. Friedländer pneumonia. B. Friedländer was found in pure culture in the sputum, which contained no acid-fast organisms. Successive sputa contained progressively fewer B. Friedländer in mixed culture; no typing was performed. Prostatic smear, urinalysis, serologic tests, blood sugar, sedimentation time, and brucellosis agglutination tests were negative as was hemocytology except for leukopenia of 4,500; 0.0002 mg. P.P.D. produced a 2+ reaction.

The patient had a subfebrile temperature which gradually fell to normal levels. His cough slowly cleared. The exudative choroiditis showed progression in extent and severity, at one point suggesting early proliferating retinitis.

The morphologic, cultural, manifold pathologic, and serologic properties of B. Friedländer or *Bacillus mucosus capsulatus* were discussed. The unusual, chronic type of pneumonia caused by this organism is quite consistent with the clinical picture presented by this patient. People in the younger age groups are found to have a definite resistance to the organism.

Investigations of the pathogenesis of uveitis rarely unearth evidence susceptible of scientific proof as attested to by Berens *et al.* in their negative blood, aqueous, and pharyngeal cultures including virus and brucellae in 91 such patients. Morphologic or cultural proof of actual uveal invasion of an organism is rare, as is evidence of direct irritation by bacterial endo- or exotoxins. Hypersensitivity to allergins produced by bacterial foci rests on evidence chiefly of a clinical nature, and admits of wide divergence of

opinions as to the relative importance of pyogenic foci and tuberculosis and syphilis.

In summary, this patient with exudative choroiditis presented an unusual variety of possible etiologic factors, including a B. Friedländer pulmonary infection.

Discussion. Dr. W. E. Fry said that he examines these cases of exudative choroiditis very carefully in the hospital, and it has been his experience, and it probably corresponds to that of others, that in a number of cases the cause is not found, or that the cause of the ocular difficulty cannot be definitely ascertained. This case falls in just the opposite group. There are so many causes for the exudative choroiditis that any one can be chosen. The present findings, although not absolutely definite, suggest that the real cause is a pulmonary complication.

EPIBULBAR TUMOR—CASE REPORT

DR. W. E. FRY presented the case of a 62-year-old woman who, in April, 1915, first noted a small pigmented lesion at the limbus of her left eye at the 1-o'clock position. In October, 1916, the lesion measured 4.5 by 2.5 mm. and extended 1.5 mm. onto the cornea. The nodule was excised in January, 1920, and the pathologic report was melanosa sarcoma. The nodule was excised a second time, and the thermophore was applied three times. The lesion recurred locally, and travelled about the limbus in a counter-clockwise direction. He stated that the patient then reported to him for treatment and the eye was enucleated in April, 1941. There was no evidence of metastasis and the patient remained well.

A pathologic report of the enucleated eye was made. The section of the eye revealed a deeply pigmented tumor mass near the periphery of the cornea. The mass in the section measured 3 mm. It

was composed of pigmented, elongated spindle cells. The nuclei were deeply stained and varied moderately in size. The associated inflammatory reaction was shown by clusters of polymorphonuclear cells. All of this tumor mass was superficial to Bowman's membrane. The tumor mass was partly divided by a band of dense connective tissue. All of the superficial portion of the cornea was involved to a varied degree by tumor cells. These were seen at places within as well as below the epithelium, and beneath superficial bands of connective tissue. A band of partly hyalinized connective tissue spread across the cornea above Bowman's membrane. Bowman's membrane was unbroken, and the stroma beneath it appeared normal.

The remaining portions of the eye were uninvolved with one exception; there was an unusual number of pigment granules in the corneoscleral trabeculae.

Conclusion. Certain portions of this report may be emphasized. The case described had been followed for 28 years. The tumor was of a type ordinarily considered highly malignant, melanosarcoma or malignant melanoma. In spite of the recurrences, final pathologic examination revealed that the corneal involvement was entirely superficial. There had been no distant metastasis—had there been this patient would have died years ago. The tumor apparently possessed only the property of local recurrence.

An additional point of interest is that,

although the cornea under the microscope appeared remarkably clear, visual acuity was below 6/60. This is of importance in correlating experimental corneal disease, and the effective result of treatment.

Discussion. Dr. James S. Shipman asked Dr. Fry why radium was not used in the case reported, and what might have been the result if radium had been used. In most of the cases seen at the Wills Hospital irradiation before excision is advised and has been followed quite routinely for epibulbar growths. After excision, a correct diagnosis can be made, and further irradiation carried out if indicated.

He said that it has been stated that Colonel Ash thought irradiation unnecessary in carcinoma. He said that he would like to know why that is true, and if the same thing is true in cases of melanosarcoma.

Dr. Fry, in closing, said that this patient had been seen at the X-ray Department at the University and irradiation was contraindicated. He stated that he thought Dr. Shipman was quite correct as far as the opinion of some doctors is concerned. For instance, Dr. Reese in a recent discussion of treatment of precancerous melanosis of the conjunctiva recommends excision and irradiation by applying radon directly to the site of the growth.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.
Address original papers, other scientific communications including correspondence, also books for review to Dr. Lawrence T. Post, 640 South Kingshighway, Saint Louis 10, Missouri; Society Proceedings to Dr. Donald J. Lyle, 904 Carew Tower, Cincinnati 2, Ohio. Manuscripts should be original copies, typed in double space, with wide margins.
Exchange copies of medical journals should be sent to Dr. William H. Crisp, 530 Metropolitan Building, Denver, Colorado.
Subscriptions, applications for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.
Author's proofs should be corrected and returned within forty-eight hours to the Manuscript Editor, Miss Emma S. Buss, 5428 Delmar Boulevard, Saint Louis 12, Missouri. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

PSYCHOLOGY AND EYE EXERCISES

Every day, thousands of patients throughout the land ask their oculists for an opinion on the value of "eye exercises." These questions are based upon statements read in books or magazine articles; or upon the extravagant claims made by the least scientific and the least scrupulous of optometrists, or by practitioners of medical heterodoxies who see a chance to profit by public interest in the subject.

The average patient or parent asking such a question has only very faint no-

tions as to a distinction between the application of the term "eye exercises" to the direct function of vision on the one hand, and its use with regard to the behavior of the muscles which move the eyeball, or to the function of binocular vision, on the other hand. It must be recognized, also, that some general physiicians are not much more enlightened in this respect than the average layman. Yet the distinction is important.

In the popular press and the public mind, most of the recent trumpeting as to eye exercises relates to the supposition that optical defects of the globe, produc-

ing nearsightedness or farsightedness or astigmatism, may be corrected without the wearing of glasses, by resort to the so-called exercises advocated by Bates and his followers, of whom one of the latest is the visually handicapped novelist and essayist Aldous Huxley.

The public mind has displayed a much less significant interest in orthoptics, which aims to remedy defective control of the muscles that move the eye, or faulty association between the two eyes as to the function of binocular vision. This lesser display of interest depends mainly upon the fact that only a relatively small number of people are directly affected by the problem, whereas a very high percentage of the population is faced by the need for wearing glasses to compensate for errors of refraction.

Eye physicians have rather generally favored the attempts to improve external muscular control, and the function of binocular vision, by the type of eye exercises known as orthoptic training, although many eye physicians are still rather doubtful as to the frequency with which substantial and lasting benefit is derived from such training. The claims put forward as to exercises associated with the names of Bates and Huxley are condemned by the overwhelming majority of eye physicians as false, unscientific, and often dishonest. Eye physicians generally, from their understanding of the structure and physiology of the eye, know that it is ridiculous to suppose that any such system of eye exercises could so change the length of the eyeball or the curvature of its essential structures as to overcome the need for glasses to correct farsightedness, nearsightedness, and astigmatism.

At the 1943 meeting of the American Academy of Ophthalmology and Otolaryngology, Lancaster presented a paper under the title "Present status of eye ex-

ercises for improvement of visual function" (Archives of Ophthalmology, 1944, volume 32, page 167; also Transactions American Academy of Ophthalmology and Otolaryngology, 1944, 49th meeting, page 413). This paper has recently been made the subject of editorial comment in the Journal of the American Medical Association (1944, volume 126, page 771).

Lancaster emphasizes the fundamental biologic fact that repetition of an act facilitates its performance, tends to the acquisition of skill and efficiency. This principle underlies the practice of orthoptics, in which it is often necessary to replace faulty by correct habits of performance. As regards the function of binocular vision or the visual capacity of an eye which is anatomically normal, but in which poor visual acuity appears due to lack of use or lack of training of the eye and brain, the eye exercises of orthoptics may actually improve sight. To a certain degree this experience conflicts with the general rule that "the only way to improve sight is to get a better image on the retina."

The influence of cerebral training upon perception is seen in the daily phenomena of hearing, where faint sounds are recognized or interpreted through their associations. It is particularly manifest in the student of a foreign language, who may have an excellent knowledge of vocabulary and phonetics but may be utterly defeated in his efforts to grasp the sounds of the language as spoken by a native.

The same principle is illustrated in the experience of a highly intelligent blind person who has made a partial study of Braille but who tells us that he gets a false sense of competence from the fact that he is reading selections from the classics, with which he was long ago familiar, and therefore knows in advance what is coming. Give the same student of

Braille an entirely "unseen" and unfamiliar passage, and he is lost.

Lancaster's paper dismisses in very few words the structural changes, apart from those in the external muscles, which are claimed to result from "eye exercises." "Frankly," he says, "I am skeptical of such an effect." He quotes the saying of Jesus: "Which of you by taking thought can add one cubit unto his stature?" Yet the article contains two or three statements which are likely to be lifted out of their context and applied in support of the Huxley-Bates point of view. Thus we have the aphorism: "Seeing is only half ocular; the other half is cerebral." We are further told that "buried in a mass of what to ophthalmologists seem foolish gestures and performances, best defined as hocus-pocus, there are sound and fruitful ideas." Also, as to the cerebral part of ocular synthesis, it is suggested that "ophthalmologists have neglected this field and have concentrated their attention on the primary source of sensation, the image on the retina, leaving to irregular, untrained workers the cultivation of that field." The facility with which such statements may be made to assume a detached and exaggerated significance is illustrated by the fact that the short editorial comment in the *Journal of the American Medical Association* dwells chiefly upon these very passages from Lancaster's paper.

As the present writer has pointed out (*American Journal of Ophthalmology*, 1943, volume 26, page 202), "such parts of Huxley's volume as have any value at all have been lifted from the works of writers on psychology." The same is true of other advocates of the Bates system.

Physicians, outside the ranks of the psychiatrists, are pretty well accustomed to being told that they do not devote sufficient attention to the importance of psychic or psychologic influences. But it is

probable that most physicians do give more or less attention to this factor in health and disease. They could hardly be successful in handling patients if they completely ignored mental influences. On the other hand, it is possible to attach too much importance to the psychic factor. Certainly a good many followers of another eminent Bostonian carry to a ridiculous degree the emphasis on mind and a professed disregard of the material basis. The act of walking might be described as one half muscular and the other half neural and cerebral. But wasted muscles cannot produce the act of walking, no matter how perfect the nerve action or how keen the volition. In a superlative degree, good sight depends upon accurate retinal function, which in turn is influenced by the structure of cornea and lens and the length of the eyeball.

W. H. Crisp.

EYE CARE FOR OUR RETURNED SOLDIERS

All ophthalmologists are interested in the quality of the treatment being given to the wounded and diseased eyes of our returning soldiers and sailors. Col. James Greear gave a very reassuring talk on the subject as it pertains to the war blinded at a dinner at the last meeting of the American Academy of Ophthalmology and Otolaryngology. At the end of October the writer had the privilege of visiting the O'Reilly General Hospital at Springfield, Missouri, where he saw what was being done for ocular injuries and eye diseases in our soldiers from overseas. This is one of eight general hospitals that have been designated for the care of these eye cases in addition to certain other types of special work.

A good train service connects this Hospital with Saint Louis and points East, but patients are for the most part, trans-

ported to the Hospital by air, landing from ambulance planes at the nearby air-drome. They arrive from the battle fields of Europe in a surprisingly short time, often only a matter of a few days after the injury or illness is incurred.

About 250 beds of this 3,500-bed Hospital are assigned to ophthalmic patients; of these some 135 were in use on the day of the writer's visit. The Hospital is composed of a series of connecting one-story buildings of frame and composition construction. They are equipped with every modern device that would assist in the diagnosis or treatment of patients. The operative set-up is of the best, but most important of all is the well-trained personnel of the staff assigned to the care of eye patients.

The organization is fortunate in having as Commanding Officer General Foster, who has an advanced point of view as regards the whole enterprise. He has surrounded himself with capable young men and has inspired in them a fine *esprit de corps*. The eye service is also fortunate in that Lt. Col. Edward P. Burch, II, is assistant to the General, because Colonel Burch is a well-known ophthalmologist who, therefore, has an especial interest in the eye patients, although no longer in charge of the ophthalmic division. This position is now held by Major Perry, another capable ophthalmologist. Under him are Captains Swift and Sherman. The latter has responsibility for the ophthalmic plastic surgery of which there are many cases. There were approximately 40 patients undergoing this type of reconstruction at the time of the October visit. Dr. Sherman, having been trained by Dr. John M. Wheeler, was using the methods advocated by him and was doing excellent work.

One of the major eye problems in these base hospitals, where definitive treatment is carried out, is that of uveitis; many

cases are seen and every opportunity for complete studies of them is offered. This was the subject of Captain Swift's paper at the evening meeting, where he discussed 100 cases of this malady. The afternoon clinic included many patients suffering from uveitis. The etiology seemed to differ little from that found in civil life, and, unfortunately, recovery was just as slow and uncertain.

At O'Reilly General Hospital very fine work on the construction of artificial eyes from acrylic material is being done by Major Hahn of the Dental Corps. These eyes are tailormade for the patient. Excellent fits are possible because of the molding of the model in the socket. Life-like irides are painted on plug buttons which are embedded in the molds in the correct situation. Conjunctival vessels are cleverly imitated by variously colored nylon threads planted in the "scleral" surface. When asked how fragile these eyes were Major Hahn responded by throwing one of them at full force on the composition floor. It bounced 8 to 10 feet and on recovery showed no sign of the abuse. Major Hahn says that there are still some "bugs" in the process but all can probably be removed.

Taken as a whole and in every detail, ophthalmologists can rest assured that if the other seven ophthalmic bases are on a par with the O'Reilly General Hospital in care of ophthalmic cases the very best attainable is being done for our soldiers.

Lawrence T. Post.

BOOK NOTICES

THE ROMANCE OF MEDICINE. By Benjamin Lee Gordon. Clothbound, 864 pages with index and many illustrations. Philadelphia, F. A. Davis Co., 1944. Price \$5.00.

This volume should be of special in-

terest to the ophthalmologist because of the large role that eye diseases and superstitions play in the history of medicine.

The author has unearthed an amazing amount of folk-lore and historical facts about the art of healing. He has also selected an unusually pertinent collection of illustrations. No physician can fail to find much that is of great interest in the book. Undoubtedly, in such a compendious undertaking there are a number of errors, but these are of minor significance because the treatise is written presumably with the primary intention of creating interest rather than as a reference book of encyclopedic accuracy.

The chapters divide the subject perhaps a little artificially, but it is difficult to maintain an over-all continuity in a work of this kind. The reader found the book not one to be consumed from cover to cover uninterruptedly, but this is an end almost impossible of attainment in these days when every newspaper contains material so thrilling and so vital that literature other than current has difficulty holding the attention at all. Notes on each chapter precede the index.

"The romance of medicine" will be found a pleasant diversion as well as a means of agreeably enlarging one's knowledge of interesting facts in the development of medicine. Perhaps it will be most enjoyed as a book to be picked up intermittently for an hour or two's reading. The author and publisher are to be congratulated on the splendid appearance of the volume at a time when most books are made of such poor material and have such blurred illustrations that there is little hope of their survival in the libraries of the future.

Lawrence T. Post.

Portuguese.) By Octacilio de C. Lopes. Paper covers, 146 pages, 13 illustrations, Livraria Atheneu Jose Bernades, Rio de Janeiro, Brazil, 1944. Price not stated.

This well-arranged and clearly written monograph consists largely of a review of the world literature of the subject, with three important chapters devoted respectively to etiology, pathogenesis, and pathologic anatomy. A chapter of fourteen pages is devoted to circumstantial accounts of a number of cases from the author's personal experience.

W. H. Crisp.

CORRESPONDENCE

OPHTHALMOLOGY IN PARIS

November 22, 1944

Editor, American Journal of
Ophthalmology:

The first meeting of the Société d'Ophthalmologie de Paris since the Liberation was held at the Faculté de Médecine on the 31st of October, 1944. Those present were Drs. Favory (president), Prélat (secretary general), Bégue, Rollin, Guillaumat, Voisin, Desvignes, Bailliart, Légard, Chappé, Gallois, Offret, Bruneau, Kalt (the younger), Lavat, Nectoux, Mérigot, Dubois, Charpentier, Dollfus, Blum, Bollack, and Coutela. Col. Derrick Vail, Senior Consultant in Ophthalmology, E.T.O., U. S. Army, was the guest of honor. The program consisted of the following case reports and papers. "A case of grippotyphosa leptospirosis with ocular complications," by Drs. Dollfus and Denechau; "A case of severe bilateral photo-traumatic retinitis in a wounded soldier," by Dr. Dollfus; "Barbituric amaurosis with evolutionary accidents," by Drs. Offret and Ardonin; and "Spontaneous detachment of the choroid—a rare complication of furunculosis," by Dr. Hébert. Dr. Fa-

OFTALMIA SIMPATICA (SYMPATHETIC OPHTHALMIA). (In

very graciously welcomed the American ophthalmologists and invited them to attend all future meetings. There was much discussion over ways and means by which the Society could help their distressed members and confrères who had suffered loss of equipment and supplies during the Battle of France. Colonel Vail extended the sympathy of the American colleagues and requested information so that some measure of assistance might be given by the ophthalmological societies of the United States.

Undisturbed by the Huns, the Society held its meetings regularly during the occupation. Its famous Bulletin, however, could not be published due to lack of paper and authority. Several of its members suffered personal harm and damage at the hands of the unspeakable Hun. The relief of freedom and an electric feeling of joy pervaded the group.

The following is a note which Dr. Magitot wrote at my request giving information regarding his activities during the German occupation of Paris. I think this will be of interest to us in the Journal.

"Dr. Magitot sends all his American friends his kindest regards and best remembrances. He is now back in Paris. He was considered by the Germans to be a Jew by his marriage, and consequently his home, estates, books, and professional equipment were seized. To avoid deportation, all of his family scattered and had to hide during the four years. Now that liberation has come, he believes he must rejoice to find himself, wife, and children still alive.

"The eye department in the Lariboisière Hospital, where he used to work, and the Rothschild Foundation of the Rue Marin, have been taken and plundered. It will need much time before these clinics can be run again.

"The *Annals d'Oculistique* is planning

to issue a first number in January, 1945, if paper is available. During these past years in exile from Paris, Dr. Magitot has written a 'Clinical physiology' which is now being printed by Masson et Cie. Another book 'Textbook on ophthalmology,' written with Dr. Bailliart, is ready but cannot be published until paper is obtained.

"Anxious to know about the ophthalmologic activity in the States during this war, Dr. Magitot would highly appreciate it if his American colleagues would send him reprints. He is happy that he will hear from his American friends as soon as regular mail is restored."

(Signed) Derrick T. Vail.

ON DIVERGENCE EXCESS AND POSTURAL TONUS

To the Editor:

Captain Posner, in the October number of the Journal, deals with some important aspects of ocular motility but does not carry through his thinking with complete consistency perhaps because he is still under the spell of the old ideas which he is aiming to correct.

He takes as his text a case of anisometropia: O.D. +0.25 cyl. approximately emmetropic; O.S. fairly high H. As was to be expected, the tests for heterophoria give different results according to which eye is made to fixate, the tests being made without glasses. When the emmetropic right eye fixates there is no accommodation required and therefore no impulse to converge excited by accommodation. The phoria is an exophoria which is the true or underlying phoria uninfluenced by other reflexes than the basic tonus reflex and the fixation reflex from the right retina. When the hypermetropic left eye fixates a large amount of accommodation is required (probably 3D., as 2.50D. was found with the partial cycloplegia pro-

duced by homatropine, no test of accommodation at the time of measuring the refraction being recorded—unimportant perhaps). The effect of this accommodation of over 2.50D. is to excite a corresponding convergence. Result: esophoria. A not unusual finding. (If tested with correction it is certain that the correction left some uncorrected H for the accommodation to take care of.)

It is surprising that Captain Posner says nothing about this factor of the accommodation reflex as he was emphasizing the importance of the reflexes which he rightly lists as these: (1) the underlying tonus, (2) the fixation which includes the focusing, (3) the fusion. He might have cited the tendency of tonus to hold over. Thus if a person with no hyperphoria is made to wear a prism 2^Δ base down for a few hours he will show a hyperphoria for some time thereafter as the tonus required to overcome the prism persists. Similarly the accommodation necessitated by H tends to persist.

He rightly stresses the importance of abandoning the notion of position of rest. And yet he does not consistently use the preferred term fusion-free-position probably as a concession to custom. He says: "there is a characteristic 'position of rest' for each state of *activity* of the central nervous system" (*italics mine*). Obviously rest is the direct antithesis of activity. Nor does he carry through the correction of this mistaken idea of a position of rest to include the mistaken but widely prevalent idea of mechanical or anatomical factors being the fundamental cause of most cases of heterophoria and heterotropia instead of only a few.

Bielschowsky made many valuable contributions to our understanding of ocular

motility and binocular vision but his mistaken conception of a position of rest (modified later to a relative position of rest) with its corollary of the anatomical or mechanical basis of most phorias and trophias must be abandoned if we are to achieve a sound logical conception of this important subject.

I commend the following references to Captain Posner; there are passages in each of them confirming his views on position of rest and on reflexes and carrying them farther than he has done:

"Physiology of disturbances of ocular motility," Arch. of Ophth. v. 17, p. 983.

"Detecting and interpreting ocular deviations," Arch. of Ophth. v. 22, p. 867.

"Ocular motility," Amer. Jour. Ophth., v. 24, pp. 485, 619, 741.

"Terminology in ocular motility," Amer. Jour. Ophth., v. 26, p. 122.

Walter B. Lancaster, M.D.
Boston, Mass.

CORRECTIONS

November 10, 1944

Editor, American Journal of Ophthalmology:

The following errata appeared in my paper "Backflow phenomena in aqueous veins."

On page 1078, in table 2, the number of "negative eyes" should read 30 (namely 23 plus 7), not 20.

On page 1088, ninth line from bottom of page: instead of "2. that along the convex border," should read: "2. that along the concave border." The word "convex" in the neighboring line, however, is correct.

(Signed) K. W. Ascher.

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

CORNEA AND SCLERA

Krutova, A. H. Sulfanilamide in the treatment of corneal ulcers. *Viestnik Oft.*, 1943, v. 22, pt. 3, p. 43.

In the treatment of corneal ulcers Krutova found local application of sulfanilamide powder more effective than the application of any other therapeutic agent. It cleanses the cornea of purulent infiltrates, and pain is relieved in one day. The drug has no effect on hypopyon, which may continue to increase in spite of the fact that the ulcer is getting clean. Final cicatrization of the ulcer is delayed longer than usual, and epithelization still longer. Apparently sulfanilamide retards the regenerative process. Ray K. Daily.

Scholz, R. O. Unsuccessful treatment of syphilitic interstitial keratitis with sulfanilamide. *Arch. of Ophth.*, 1944, v. 32, July, pp. 68-69.

In view of the conflicting reports in the literature, four patients with congenital syphilitic interstitial keratitis

were treated in the Johns Hopkins Hospital with ordinary antisyphilitic therapy plus sulfanilamide in large doses. In none of the cases was there any significant improvement which might be attributed to this therapy. One of the patients was also given a second course of treatment with sulfanilamide plus riboflavin, without result. The four cases are reported individually. (References.)

R. W. Danielson.

Strakov, V. P. Ophthalmic successes in corneal transplantation. *Viestnik Oft.*, 1942, v. 21, pt. 6, p. 28.

The wide application of corneal transplantation dates from 1924, when Filatov and his coworkers at the Ukraine Research Institute began to work on the technique of the operation, and interested a number of ophthalmologists in the work. They developed a suitable instrumentarium, and issued numerous publications on the various aspects of this type of surgery.

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Figueiredo, N. P. de. **Subsalicylate of bismuth in treatment of luetic internal ophthalmoplegia.** *Rev. Brasileira de Oft.*, 1944, v. 3, Sept., pp. 3-11.

A white soldier aged 25 years, suffering from severe dental caries, noticed in the right eye a disturbance which interfered with vision for close work. The right eye showed vision of two thirds for distance, but needed plus 3.25 sphere to obtain normal vision at the reading range. The left eye had normal vision for both distance and near. In the right eye the pupillary reflex to light and accommodation, both direct and indirect, was absent. All these reflexes were normal in the left eye. Attention was first directed to the diseased teeth, but no improvement had occurred after an interval of one week. The Kahn blood test proved strongly positive, and the patient was given a course of intramuscular injections of subsalicylate of bismuth, one c.c. weekly. Improvement was noted soon after the sixth injection, and the Kahn test was then negative for the first time. Four days after the tenth injection, the Kahn was still negative, and vision was normal for both near and distance, with normal pupillary reflexes.

Kinsey, V. E., and Grant, W. M. **The secretion-diffusion theory of intraocular fluid dynamics.** *Brit. Jour. Ophth.*, 1944, v. 28, July, pp. 355-361.

This paper is a recapitulation of the authors' theory of intraocular fluid dynamics, and a discussion of criticisms made by Duke-Elder and Davson of the mathematical concepts used in developing the theory.

It was found that the total water movement into and out of the anterior chamber of the rabbit was approximately fifty c.mm. per minute, a rate far in excess of what was thought to be the rate of formation of the aqueous humor as a whole. This is believed to suggest that perhaps the various constituents of the aqueous humor may enter the anterior chamber at different rates. To test this hypothesis, the rates of accumulation of various substances in the anterior chamber were determined, as was also the concentration of these substances in the plasma. It was found that electrolytes entered the anterior chamber as a result of secretion, while nonelectrolytes entered by diffusion. It is believed that both electrolytes and nonelectrolytes leave the anterior chamber by a process of flow. (References.)

Edna M. Reynolds.

Wagener, H. **Toxoplasmic chorioretinitis.** *Amer. Jour. Med. Sciences*, 1944, v. 208, Aug., p. 255.

The rather recent discovery that the toxoplasma, a highly organized protozoan parasite, can invade the tissues of the eye and cause destructive lesions of the choroid and retina, has introduced further complexity into the etiologic study of chorioretinal disease. The author reviews cases from many references, with opinions of various authors on the subject, and particularly quotations from a recent article by Vail. There is a predilection for the macular area, and the lesions are usually bilateral and multiple. Diagnosis from the ophthalmoscopic appearance alone appears indefinite. The decision may depend upon demonstration of neutralizing antibodies in the blood serum. A positive complement-fixation reaction does not in all cases indicate active or even recent infection. There

seems to be no very satisfactory treatment, though various forms of sulfonamide have been tried.

GLAUCOMA AND OCULAR TENSION

Ascher, K. W. **Backflow phenomena in aqueous veins of normal and of glaucomatous eyes.** Amer. Jour. Ophth., 1944, v. 27, Oct., pp. 1074-1089. (4 figures, 3 tables, 3 in color, references.)

Bertotto, E. V. **Chronic simple glaucoma.** Anales Argentinos de Oft., 1943, v. 4, Oct.-Nov.-Dec., pp. 152-166.

The author accepts Magitot's inclusive definition of chronic simple glaucoma as an affection characterized by a particular optic nerve atrophy, circulatory modifications, and intraocular hypertension. Among disputed initiating factors are endocrine instability and neurovegetative derangement. The theories of pathogenesis include the circulatory, the hypersecretive, and the theory of diminished fluid absorption (or mechanical theory). There are found differences of opinion as to whether to operate early or late. The author feels that surgery is definitely indicated when the visual fields continue to contract in the face of topical medical care. (One table, fields).

Evans, J. N. **The macula-wedge scotoma a prognostic index in glaucoma.** Amer. Jour. Ophth., 1944, v. 27, Oct., pp. 1090-1093. (2 figures.)

Gartner, S., and Lambert, R. K. **Tenotomy of the rectus muscles in glaucoma.** Amer. Jour. Ophth., 1944, v. 27, Nov., pp. 1228-1231. (References.)

Hess, Leo. **Pathogenesis of acute glaucoma.** Arch. of Ophth., 1944, v. 32, Aug., pp. 128-132.

According to the author, acute glaucoma may be viewed as a vegetative neurovascular crisis. Other examples of this kind of crisis are epileptic seizures and attacks of cardiac asthma associated with acute edema of the lungs. The ciliary ganglion and the vegetative diencephalic center at the base of the brain (the Karplus-Kreidl center) are thought to play predominant roles in the nervous mechanism of glaucoma. The increased intraocular pressure and many other signs of acute glaucoma are secondary to the central irritation. The congestion of the conjunctival blood vessels, chemosis, edema of the lids, and changes in the cornea commonly regarded as inflammatory, are really of angioneurotic origin. The pharmacologic aspects of this concept are discussed. (References.)

John C. Long.

Paulo, A., Jr. **Late suppurative infections after fistulizing operations.** Rev. Brasileira de Oft., 1943, v. 1, June, pp. 193-208.

Two cases are recorded. The first patient, aged fifty years, underwent an Elliot trephining, followed by a small cyclodialysis through the scleral opening. The patient refused removal of a dental abscess. After six weeks he returned with acute signs of uveitis, including cloudiness of the anterior chamber, a small hypopyon, and a purulent appearance of the cystoid scar. The tension, previously normal or less, had risen to 22 mm. (Schiötz). A variety of medicinal and surgical procedures proved ineffective, and the eye had to be enucleated in a condition of painful atrophy, with suspicion of

sympathetic ophthalmia in the other eye.

The other patient, a man of 72 years, also underwent an Elliot trephining. Many months later he returned with an acute uveitis. Bacteriologic examination revealed the presence of a hemolytic streptococcus. In this patient, also, a dental abscess was found after the development of the acute inflammation, but evisceration proved necessary in spite of extraction of the tooth. (2 drawings.) W. H. Crisp.

Pletneva, H. A. Contributions to the study of glaucoma during the last twenty-five years. *Viestnik Oft.*, 1942, v. 21, pt. 6, p. 21.

A review of the contributions of Russian ophthalmologists in this field. Maslennikov was the first to call attention to the diagnostic importance of the daily tension curve. Samoilof described the variations in the size of the blind spot under the influence of pilocarpine, and made a comprehensive study of hypertension as a reaction to pain. Kamenetzki described an unusual form of glaucoma, observed in the Irkutsk district; it occurs only in young men, is associated with atrophy of the iris, and is inherited. Pilman studied the influence of the thyroid on glaucoma. In 99 percent of the glaucoma patients he found hypothyroidism, and the blood serum of these patients added to atropine produced maximum dilatation of the pupil. Blood serum of hyperthyroid patients inhibited the action of atropine. Fradkin, in a study of the mechanism regulating intraocular tension, pointed out the importance of conditioned reflexes. Impulses from the cortex may change so fundamental a property of cells as their permeability. The reflex rise in

intraocular tension in response to a conditioned reflex indicates cerebral participation in the regulation of intraocular tension. Maklakov was the first to conceive the idea of a subconjunctival fistula in the treatment of glaucoma. Filatov demonstrated the effect of muscular exercise on intraocular tension. From Kravkov's laboratory of physiologic optics came interesting data on the effect of white and green illumination on intraocular tension.

Ray K. Daily.

Promptov, B. A. A new miotic—proserin. *Viestnik, Oft.*, 1943, v. 22, pt. 3, p. 33.

To encourage the production of proserin, which is the Soviet drug with the chemical formula of prostigmin, the author reports its effect in clinical cases. The conclusions based on the clinical applications are that a 5-percent solution instilled into the conjunctival sac produces contraction of the pupil, and reduction of intraocular tension in glaucomatous eyes. In some cases the pupil contracts but intraocular tension remains uninfluenced. This drug does not produce the painful sensation in the eyes and temples sometimes caused by eserine.

CRYSTALLINE LENS

Bailey, J. H. A modification of the corneal section in the operation for cataract. *Amer. Jour. Ophth.*, 1944, v. 27, Nov., pp. 1253-1257. (2 figures.)

Lawes, F. A., and Halliday, J. C. Marfan's syndrome: arachnodactyly with dislocation of the crystalline lens. *Med. Jour. Australia*, 1944, v. 1, May 20, p. 465.

After an introduction regarding the history and symptoms of the disease, the authors report three cases in one family. A woman aged 52 years had "trouble with her spine" at the age of seven years, and now has a dorsal curvature of the upper thoracic portion of the spine, so that she is at present 5 feet 9 inches as against earlier 5 feet 11 inches. The sternum is unduly prominent, the hands and feet much elongated. Each forefinger measures 4 inches, the second finger 5 inches, the third $4\frac{1}{2}$, the fourth 3 inches. The length of the great toe is $3\frac{1}{2}$ inches, that of the second toe also $3\frac{1}{2}$ inches. X-ray examination of the thoracic part of the spine reveals a destructive lesion (probably healed tuberculosis) at the level of the seventh thoracic vertebra. The patient is now in good health. Her ocular conditions are: pronounced iridodonesis, dislocation of the lenses upward, visual acuity 6/36 and 6/24 unimproved by glasses. A girl aged 14 years, otherwise well built, has rather long fingers. When her pupils are dilated iridodonesis can be observed, with slight dislocation of both lenses upward. She has compound myopic astigmatism, and with correction her visual acuity is 6/9. The third patient, a boy aged six years, looks older than his age and his face longer

than in normal proportion. Notable features are long fingers and toes and winged scapulas. The chief complaint was of bad vision, and on examination pronounced iridodonesis was found, with dislocation of both lenses upward. M. Lombardo.

Lijó Pavía, J., and Morate, F. H. Senile cataract and vitamin C. *Rev. Oto-Neuró-Oft.* 1944, v. 19, May-June, pp. 84-88; also *La Semana Med.*, 1944, v. 51, Aug., pp. 275-277.

This short paper is a sequel to one written by Lijó Pavía seven years ago. The majority of cataract patients have a vitamin-C deficiency, and the elderly require more vitamin C than the young. The authors administer vitamin C perorally, intravenously, and in certain cases into the anterior chamber. In their series of selected cases of immature senile cataract, definite improvement in visual acuity was noted after vitamin-C treatment. In cases of mature cataract, however, the improvement was slight and was seen in but a few instances. Edward Saskin.

10

RETINA AND VITREOUS

Arruda, Jonas de. Comments on gravidic retinosis. *Rev. Brasileira de Oft.*, 1943, v. 1, June, pp. 223-232.

Three cases are described. A woman of 28 years, previously normal, developed an acute nephritis at three months of pregnancy. The vision of each eye was one fortieth, the arterial pressure 190/120 mm. The fundi showed numerous exudative lesions, with intense retinal edema and a number of hemorrhagic foci. The ocular condition improved rapidly after surgical termination of the pregnancy, the

vision rising to right 9/10, left 8/10. But the nephritis advanced and the patient died about six months later.

The second patient, a woman of 32 years, had been found in normal condition shortly before the end of her third pregnancy. Fifteen days before the birth of the child, she noticed a rapid falling off in the vision of the left eye, the only eye in which it was possible to see the fundus or which had previously possessed good vision. The patient had the usual symptoms of headaches, dizziness, and vomiting. After parturition, she was given intense antiluetic and vitamin treatment, without result. The vision of the formerly good eye was reduced to counting fingers at one meter, and the fundus showed extensive disturbance of the macular area, including white spots and discrete pigmentation. Nine months later the eye developed a retinal detachment. (References.)

W. H. Crisp.

Brickner, R. M. Visible retinal arteriolar spasm associated with multiple sclerosis. *Arch. Neurol. and Psychiatry*, 1944, v. 51, June, p. 573.

The authors have noted a phenomenon, associated with multiple sclerosis, which so far as they know has not been previously described. In association with abrupt attacks of visual impairment consisting of shimmering and the presence of multiple dark areas, spasm of the retinal arterioles could be seen on examination with a Morton ophthalmoscope. In two cases of multiple sclerosis, spasm of the retinal arterioles was coincident with the presence of scotomas. When the scotoma receded or disappeared, the spasm also disappeared; this change followed immediately the inhalation of amyl nitrite in one case and was spontane-

ous in the other. In a third case, attacks of blurred vision were promptly relieved by inhalation of amyl nitrite.

Theodore M. Shapira.

Goldberg, S., and Newell, F. W. Sarcoidosis with retinal involvement. *Arch. of Ophth.*, 1944, v. 32, Aug., pp. 93-96.

The iris is very commonly involved in sarcoidosis whereas infiltration of the choroid and retina is rare. The authors report two cases of sarcoid with fundus lesions. The first patient was a 23-year-old Negro male who had noticed nodular swellings in both inguinal regions, followed by enlargement of the parotid, posterior cervical, axillary, subclavicular, and epitrochlear glands. A marked reduction in vision of the right eye was noted. The right eye showed much pigment and many blood cells in the anterior portion of the vitreous. There were many deep and superficial retinal hemorrhages, with thrombosis of the superior temporal vein. The macular area was edematous. Six weeks later, a white mass, extending 3 diopters into the vitreous, was present at the inferior nasal margin of the disc. The mass was superficial to the retinal vessels but was overlain by many new vessels. Chest X-rays showed adenopathy of the hilar nodes of both lungs and a generalized increase in lung markings. Biopsies of the enlarged lymph glands are typical of Boeck's sarcoid.

The second case was found in a 24-year-old Negro male. There was marked parotid swelling, swelling in the upper outer angle of the orbits, cervical adenopathy and subcutaneous nodules in the arms and forearms. The right optic disc was obscured in the inferior nasal quadrant by a grayish-

white mass approximately 2 disc diameters in diameter and extending nasalward. The mass overlay the retinal blood vessels and projected 4 diopters into the vitreous. Subhyaloid and retinal hemorrhages were present. Biopsies from the enlarged glands were somewhat atypical but were interpreted as representing sarcoid of the Darier-Roussy type. (References.)

Guerry, DuPont, 3. Congenital retinal folds. *Amer. Jour. Ophth.*, 1944, v. 27, Oct., pp. 1132-1135. (One illustration, references.)

Lijó Pavía, J. Diathermic surgery of the retina. *La Semana Méd.*, 1944, v. 51, Sept. 21, pp. 606-610.

Two cases are reported, one of retinal detachment successfully treated with diathermy puncture, the other a case of Coats's disease (retinitis exudativa externa), in which the progress of the retinal disease appears to have been arrested by a similar delimiting use of the method, somewhat as recorded by Lewis, and in discussion by Guyton (*Trans. Amer. Acad. Ophth. and Otolaryng.*, 1943, May-June, pp. 357 and 360). (References.)

W. H. Crisp.

Lijó Pavía, J. Senile degeneration of the retina. *Rev. Oto-Neuro-Oft.*, 1944, v. 19, May-June, pp. 73-81.

The senile retinal change most often seen is atrophy of the outer layers of the retina, making readily visible a red, sclerotic choroid. Cystoid degeneration, macular degeneration and holes, and paramacular changes follow in order of frequency. Less frequent are pigmentary derangements such as the salt-and-pepper fundus, or pigmentary clumping, and senile exudative macu-

lar lesions. Three cases are reported representing respectively choroidal sclerosis and pigmentary atrophic changes, hypertensive and sclerotic retinal and choroidal lesions, and retinal endarteritis with partial obstruction. The accompanying serial retinographs are excellent. All three cases were given, among other things, vitamin-C therapy. Edward Saskin.

Lyle, D. J. The association between retinopathies and encephalopathies in the common cardiovasculorenal affections. *Amer. Jour. Ophth.*, 1944, v. 27, Nov., pp. 1232-1252; also *Trans. Amer. Ophth. Soc.*, 1943, v. 41, p. 541. (2 charts, 44 figures.)

Rebello, Orlando. Regarding circinate retinitis. *Rev. Brasileira de Oft.*, 1943, v. 1, June, pp. 213-218.

A woman aged 35 years had normal visual acuity in the right eye, but only one-eighth in the left eye. The macular area of the left eye showed grayish spots, and the lower half of its circumference had a halo of milky-white dots, which reached to the vicinity of the optic disc. Near the edge of the halo there was a broken line of fine pigment, while within the circumference there were discrete hemorrhagic spots. Retinal veins of normal aspect passed over the halo of dots, without showing any modification in their course. (One illustration.)

Rocha de Souza, Admardo. Embolism of the central artery of the retina. Treatment with retrobulbar acetylcholine. *Rev. Brasileira de Oft.*, 1943, v. 1, June, pp. 219-224.

The drug was administered by retrobulbar injection, at intervals of 12 hours, and using one c.c. at each in-

jection. Enormous edema of the eyelids occurred almost immediately after the injection. But within a few hours the vision had risen from shadows to one third. Later the vision reached normal. The 1 c.c. of the drug is combined with 0.5 c.c. of a one-percent solution of novocaine. W. H. Crisp.

Von Sallman, L., Meyer, K., and Di Grandi, J. Experimental study on penicillin treatment of ectogenous infection of vitreous. *Arch. of Ophth.*, 1944, v. 32, Sept., pp. 179-189.

From previous research, the authors had concluded that the present potent and less toxic antibacterial agents, such as the sulfonamide compounds and penicillin, introduced iontophoretically and supplemented by systemic treatment, did not check experimental endophthalmitis when the infection had spread from the anterior segment to the vitreous space. Failure attended attempts to increase the concentration of sulfadiazine in the vitreous by transscleral iontophoresis. Penicillin, also, did not enter the vitreous in detectable amounts with either local or systemic administration. Because of failure of the aforementioned methods to produce adequate concentrations of chemotherapeutic agents in the vitreous, direct injection of the drug into the vitreous space, hazardous as it seemed, was considered as a possible approach.

A single injection of 0.2 c.c. of a solution containing 2.5 mg. of sodium penicillin per c.c. into the vitreous of rabbits secured bacteriostatic activity of the vitreous fluid for more than 24 hours. Approximately the same concentrations of penicillin and sulfacetimide were found in the aqueous of rabbits after iontophoretic application of a solution containing both their sodium salts as after iontophoretic ap-

plication of a solution containing the individual salt. Topical treatment with penicillin and sulfacetimide, supplemented by systemic administration of sulfadiazine, was not more effective than local penicillin therapy in the treatment of an experimental intraocular infection with one strain of *Staph. aureus*. (2 tables, References.)

OPTIC NERVE AND TOXIC AMBLYOPIAS

Greeves, R. A. Retrobulbar optic neuritis: a pathognomonic sign. *The Lancet*, 1944, v. 246, June 3, p. 715.

The writer calls especial attention to one symptom which does not seem to be so commonly known as the other symptoms of the early stages of acute retrobulbar optic neuritis, including the central scotoma, partial dilatation of the pupil, and sensation of pain when the eyeball is moved. The other symptom consists in a tenderness usually experienced only when pressure is applied to the upper surface of the eyeball but limited to a spot in the middle line corresponding roughly to the site of the attachment of the superior rectus tendon. The writer regards its presence as pathognomonic of retrobulbar neuritis. The textbooks merely mention that the eyeball is tender on pressure, without specifying a limited area. The symptom is present only in the early stages of the disease. Like pain on movement, it disappears in a matter of days. M. Lombardo.

Hammes, E. M. **Papilledema in optic neuritis and tumor of the brain.** *Med. Clinics North America*, 1944, p. 957.

The presence or absence of physiologic cupping is not a reliable criterion for differential diagnosis, for glial excess on the disc, or colloid deposits, may cover such cupping. More important in differentiating between choked disc and optic neuritis is the duration of symptoms, longer in choked disc, shorter in neuritis. Other signs discussed are headache, visual acuity, visual field, blind-spot enlargement, and X-ray evidence of tumor.

R. Grunfeld.

Scott, J. G. **Eye changes in trypanosomiasis.** *Jour. Tropical Med. and Hygiene*, 1944, v. 47, May, p. 15.

The author examined 150 patients infected with *Trypanosoma Gambiense*. Keratitis due to the disease was not common. Chorioretinitis and optic atrophy were not seen. Iridocyclitis, characterized by keratic precipitates out of proportion to the mild ciliary inflammation, was present in four hospitalized cases. Bilateral optic atrophy followed tryparsamide treatment in one case. The author recommends testing the visual acuity before each tryparsamide injection. R. Grunfeld.

Tassman, I. S. **Foster Kennedy syndrome with fusiform aneurysm of internal carotid arteries.** *Arch. of Ophth.*, 1944, v. 32, Aug., pp. 125-127.

The syndrome of Foster Kennedy has usually been considered to be indicative of a basofrontal tumor. Several cases have been reported in which the condition arose from non-neoplastic diseases involving the blood vessels. The author describes a case of this type in a woman of 32 years. Pain in the left eye was followed by progres-

sive failure in vision of that eye. When examined nine months after onset of the illness, the vision of the right eye was 6/6 partly and that of the left eye ability to see hand movements at 12 inches. The right eye showed a definite papilledema measuring 3 diopters, with marked blurring of the margin of the disc. The left eye showed a white disc with slightly blurred margins and deep central excavation. General neurologic examination revealed no other abnormality. Encephalography showed lack of sharpness of the extreme anterior horn of the lateral ventricles. Upon craniotomy on the left side, a fusiform aneurysm of the internal carotid artery was found. It was impossible to do anything to the vascular lesion on that side. At a later right craniotomy the optic nerve was found to be pressed against the upper margin of the optic foramen. To relieve this condition the roof of the optic canal was removed for approximately a half inch. From direct surgical inspection supplemented by arteriography with diodrast, it was possible to make a diagnosis of fusiform aneurysm of both internal carotid arteries, with formation of anomalous loops in the course of the arteries and compression of the optic nerves. The vision of the right eye continued to fail, so that at the last examination it was 5/200, with extensive field constriction. (References.)

VISUAL TRACTS AND CENTERS

Engel, G. L., and others. **A migraine-like syndrome complicating decompression sickness.** . . . *War Med.*, 1944, v. 5, May, pp. 304-314.

The writers describe the clinical features of this syndrome, present data

relevant to its mechanism, and direct attention to the striking similarity which the syndrome bears to clinical migraine. Visual disturbances are common among subjects experiencing decompression sickness during exposure to simulated high altitudes in a decompression chamber. These are scotomas followed by headaches and other neurologic signs such as pareses, sensory disturbances, and aphasia which are also followed by headaches. The report is based on a total of 1,361 exposures to simulated altitudes of 30,000 to 38,000 feet, in 155 subjects. Seventeen subjects experienced the reaction. The symptoms occurred repeatedly in some persons and not at all in others. Visual-field studies revealed that the scotomas were homonymous and shifted rapidly in position. Headaches were always contralateral to the scotomas, began when the latter disappeared, and were sometimes associated with nausea and vomiting. Electroencephalograms taken during this reaction revealed abnormalities in the cortex corresponding to the focal neurologic signs. Evidence is presented that this reaction is mediated through a vascular mechanism. (2 case reports, 4 charts.)

EYEBALL AND ORBIT

Gonçalves, Paiva. Comments on a case of pulsating exophthalmos. *Rev. Brasileira de Oft.*, 1943, v. 1, June, pp. 179-191.

The patient, a young Negro, attempted suicide by firing a revolver into the right ear. Some time later he underwent a lengthy operation for extraction of fragments of the petrous portion of the right temporal bone, as well as the bullet. Four months later

the eye on the same side protruded and was congested; and a week later there was neuromyolytic keratitis and an angioneurotic edema. The eye turned inward. The visual acuity varied from nothing to one-sixth. In the course of two weeks the exophthalmos on the right side amounted to 28 mm., and the left eye developed exophthalmos of 14 mm., increasing to 24 mm. The author believes that the exophthalmos was not an indirect result of the operative interference, but arose from traumatism produced by the revolver shot. Ultimately the symptoms, which also included a bruit, were relieved by tying the internal carotid. (One photograph.)

W. H. Crisp.

Goodhill, V. Penicillin treatment of cavernous sinus thrombosis. *Jour. Amer. Med. Assoc.*, 1944, v. 125, May 6, p. 28.

In a child five years of age bilateral cavernous sinus thrombophlebitis was cured by administration of penicillin intravenously. Improvement was noted within twelve hours after institution of the treatment. Preliminary treatment with heparin and sulfathiazole had been of no avail. (3 figures.)

Robert N. Shaffer.

Kolen, A. A. A knife hook for section of the recti muscles in enucleation. *Viestnik Oft.*, 1943, v. 22, pt. 3, p. 18.

The author sharpens the inner edge of a strabismus hook, which after being introduced under the muscle shaves it off from the sclera. He claims that its use dispenses with the need for an assistant in doing an enucleation.

Ray K. Daily.

Krause, A. C., and Rosenberg, W. Treatment of metastatic meningococ-

cic endophthalmitis. Arch. of Ophth., 1944, v. 32, Aug., pp. 109-112.

A girl of 18 years, with meningo-coccic meningitis, was admitted to the hospital on the fourth day of illness. Both corneas were cloudy and the eyes were red. Treatment consisting of administration of antimeningococcic serum and of sulfadiazine resulted in recovery from the meningitis. On the twenty-third day of the illness both eyes showed serious damage from endophthalmitis, with vision reduced to perception of hand movements at three feet. The scleras were very red. The corneas and anterior chambers were extremely hazy and the pupils were irregularly dilated and adherent to the lenses. A yellow exudate behind each lens made the details of the fundi invisible. Sulfadiazine orally and atropine sulphate locally were applied. Penicillin was administered by iontophoresis for approximately a month. Typhoid vaccine was used intravenously on two occasions.

Within three months of the onset of the disease the vision of the right eye had improved to approximately 20/30. The left retained only perception of hand movements. The right eye appeared essentially normal except for posterior synechiae and vitreous haze. The left eye was slightly softer than the right and contained a dense white mass in the pupillary space. The authors consider that sulfadiazine and penicillin were the deciding factors in the improvement in this case. A remarkable feature was that the disease had been present for 24 days without remission before improvement occurred. (References.)

EYELIDS AND LACRIMAL APPARATUS

Maggi Zavalia, J., Zurbriggen, M. B., and Russo, O. Ophthalmoplegic form of myasthenia gravis. Anales Argentinos de Oft., 1943, v. 4, Oct.-Nov.-Dec., pp. 143-151.

The authors consider this condition more than simply interesting, since cases of ophthalmoplegia have developed into florid myasthenias, and since, too, pharmacologic proof of an existing myasthenia can be established.

Two cases are presented. In a three-year-old male the initial symptom was sudden ptosis of the right upper lid which worsened toward the end of each day, but showed periods of remission and relapse. Complete laboratory examination yielded no abnormal findings. Temporary recovery was achieved with intramuscular prostigmine solution. An eight-year-old female showed bilateral ptosis of the upper lid, also accentuated at the end of the day. It responded to intramuscular prostigmine solution. Thus prostigmine affords pharmacologic corroboration of a suspected myasthenia gravis.

This latter disease may occur as an ophthalmoplegia, as above described, or as an amyotrophy, or in association with other syndromes. The ophthalmo-

plegic form is the most readily studied. The prognosis depends on the type of myasthenia, the ophthalmoplegic type being compatible with long life. The etiology is obscure. (2 illustrations, references.)
Edward Saskin.

Morgenstern, D. J. Intranasal drainage for cure of chronic infection of the tear sac. *Arch. of Ophth.*, 1944, v. 32, Aug., pp. 101-103.

The author describes his technique for producing a fistula between the tear sac and the nasal cavity. A thin knife, insulated except at the tip, is passed through the dilated canaliculus into the sac and the medial wall of the sac is then incised. An inverted-U-shaped incision is made under the guidance of the palpating forefinger placed over the sac. To assure complete continuity of the U-shaped incision, the electrocoagulating current is applied to the knife. A probe is then passed through the lower canaliculus into the bottom of the tear sac and is pushed into the nasal cavity at an angle of about 45 degrees. Using this probe as a guide, the bony lacrimal fossa is broken down as widely as possible with wire hooks. Irrigation with copious amounts of fluid then turns the U-shaped flap of the sac wall down into the newly formed bony opening into the nose. Finally electrocoagulation of the newly formed opening is carried out through the nose. This method has been found satisfactory even in shrunken and sclerotic sacs. As there is a minimum of tissue destruction and usually scarcely any bleeding, the procedure can be carried out in the office. (References.)
John C. Long.

Mutch, J. R. The lacrimation reflex. *Brit. Jour. Ophth.*, 1944, v. 28, July, 317-336.

The pathways and connections of the nerves and ganglia required for proper functioning of the lacrimation reflexes are described with diagrams. Clinical observations here reported show that the sensory or afferent pathway for reflex lacrimation is the ophthalmic division of the fifth nerve, and that the efferent pathway runs in the seventh nerve but is independent of the motor fibers of the face muscles and lies separate from the seventh nerve in the brain near the sixth nucleus and also peripheral to the geniculate ganglion. Motor impulses are shown to pass along the greater superficial petrosal nerve.

Psychic weeping is bilateral and cannot be inhibited by surface anesthesia of the conjunctiva or cornea, or by paralysis of the fifth nerve or section of the cervical sympathetic. The cervical sympathetic takes no part in reflex or psychic lacrimation. (6 figures, references.)

Reese, A. B. Partial resection of the lid and plastic repair for epithelioma and other lesions involving the margin of the lid. *Arch. of Ophth.*, 1944, v. 32, Sept., pp. 173-178.

With a series of excellent photographs and drawings, the author describes various types of operation involving halving of the lids or canthotomy with sliding of a cutaneous flap. (One reference.)

R. W. Danielson.

Silvers, S. H. *Microsporon audouini* infection of the eyelashes. *Arch. Derm. and Syph.*, 1944, v. 49, June, p. 436.

The author records the case of a white boy, 8½ years old, who had a ringworm infection of the right cheek

of about two weeks duration. Hairs of the cheek, and later some eyelashes, fluoresced under the Wood filter. Infected hairs, when removed and cultured, showed *Microsporon audouini*. At a late stage the right upper and lower lids became swollen and the conjunctiva inflamed, and under the Wood filter about one-half of the upper lashes and one third of the lower showed fluorescence. The treatment consisted of manual epilation of the infected lashes. Later examinations under the Wood filter, the first two held at weekly intervals and the last one after a month's interval, failed to show infected lashes.

Theodore M. Shapira.

Whalman, H. F. **Reconstruction of ablated lower lid.** *Arch. of Ophth.*, 1944, v. 32, July, pp. 66-67.

The method here described arose out of the necessity for extensive ablation of the lower lid in a case of basal-cell carcinoma which had grown in both directions laterally from the middle of the lower lid and had invaded the tarsal cartilage. The growth was invasive and did not subside under moderate irradiation. Since a larger dose would have resulted in destruction of the lid, excision, with a safe margin, seemed advisable. The author describes his method of transplanting a part of the upper lid to fill in the defect in the lower lid. Excellent drawings supplement the description.

TUMORS

Asbury, M. K. **Epithelial tumors of the iris.** *Amer. Jour. Ophth.*, 1944, v. 27, Oct., pp. 1094-1106; also *Trans.*

Amer. Ophth. Soc., 1943, v. 41, p. 368. (9 illustrations, bibliography.)

Rosén, Emanuel. **Bilateral teratoid tumor of the limbus.** *Arch. of Ophth.*, 1944, v. 32, Aug., pp. 120-122.

A man aged 25 years had noticed poor vision of the right eye and a peculiar appearance of both eyes as long as he could remember. The condition of the eyes had not undergone any appreciable change. The right eye showed a peculiar dusky injection of the bulbar conjunctiva and three hypervascularized masses. These masses were grayish, slightly elevated, and sharply outlined. They covered approximately 2 mm. of the cornea and extended into the cul-de-sac. The cornea was irregularly staphylomatous, the vision 5/200. The left eye showed two smaller and less vascularized masses similar to those observed in the right eye. The vision of the left eye was 20/20.

One of the masses, measuring 6 by 5 by 5 mm., was removed from the right eye. Microscopically the sections showed many loose adipose structures in which were many islands of lacrimal gland. Several areas of adipose tissue were intermixed with loose connective tissue. Three areas of cartilaginous tissue surrounded by a richly nuclear perichondrium were observed. An occasional bundle of nerve fibers was present. The description of several teratomatous tumors is quoted from the literature, as well as theories of causation. (One drawing, one photomicrograph.) John C. Long.

Rosen, Emanuel. **Nevus flammeus associated with conjunctival telangiectasia and possible early choroidal tumor.** *Amer. Jour. Ophth.*, 1944, v. 27, Oct., pp. 1143-1145. (4 figures.)

INJURIES

Brodsky, B. S. Hand magnet for removal of splinters from the eye, and some observations relative to magnet operations. *Viestnik Oft.*, 1943, v. 22, pt. 3, p. 13.

The author advocates the use of the Soviet-manufactured hand magnet in the extraction of intraocular foreign bodies. He claims that it is effective in extracting foreign bodies from the anterior ocular segment through an open anterior chamber, and is successful in diascleral extraction provided localization of the foreign body is accurate. This hand magnet is portable and independent of the electric current.

Brown, A. L., and Nantz, F. A. Corneal healing: adhesive power of aqueous fibrin in the rabbit. *Amer. Jour. Ophth.*, 1944, v. 27, Nov., pp. 1220-1224. (One figure, 2 tables, references.)

Campos, Evaldo. Cataract from industrial electricity. *Rev. Brasileira de Oft.*, 1944, v. 3, Sept., pp. 31-36.

A white workman aged 61 years, handling a 15,750-volt, 22-ampere transformer for conversion from a current of 220 into 110 volts, received a large electrical discharge and fell unconscious. He was found with the wire in contact with his forehead and with the left wrist adherent to the key of the transformer. He made almost complete recovery, except that he became progressively completely blind (time not stated). Each eye had total cataract, of a mother-of-pearl appearance, but with good light perception and projection. (2 figures.)

W. H. Crisp.

Ershkovich, I. G. Therapy with transplantation of preserved tissues pre-

liminary to surgical procedures in war injuries. *Viestnik Oft.*, 1943, v. 22, pt. 3, p. 19.

With a report of cases the author demonstrates the beneficial effect on traumatic iridocyclitis of transplantation of small segments of preserved placenta into the skin of the mastoid. In one case the procedure arrested the development of a secondary glaucoma, and the eye tolerated a subsequent iridectomy which normalized the intraocular tension and improved visual acuity to .03. In another case of traumatic iridocyclitis, with iris bombé and occlusion of the pupil, the effect of the preserved placenta was to save the eye from enucleation. The author credits this form of therapy with the favorable course of iridectomies and lens extractions following severe traumatic iridocyclitis. Poor light projection becoming normal after transplantation served as indication for iridectomy or cataract extraction which resulted in further improvement in visual acuity.

Karandasheva, K. M. Perforating ocular injuries in the material of the N Hospital. *Viestnik Oft.*, 1943, v. 22, pt. 3, p. 24.

In this special army hospital perforating injuries occurred in 41 percent of the cases, 96 percent of them being caused by fragments of mines, bombs, or grenades and 4 percent by bullets. In 17 percent of the cases both eyes were injured. In 40 percent there was total loss of vision in one eye. In 37 percent foreign bodies were found within the eye and 16 percent in the orbit. No hair or wool particles were found with the foreign bodies, even at enucleation. The lids were injured in 35 percent of the cases, the cornea in 11.5 percent, the conjunctiva in 5.5

percent, the sclera in 13.5 percent, and the eyeball was completely destroyed in 35 percent. Perforating scleral injuries were found in 35 percent of the cases. Ophthalmoscopy was possible in 27 percent of the cases. The average hospitalization time was 9 to 11 days. Eye injuries should be seen by an ophthalmologist within the first one or two days. Results were better in the injured who reached the hospital within the first 24 to 36 hours. Soldiers with eye and orbital injuries should be evacuated in the recumbent position.

Ray K. Daily.

Katznelson, A. B. Remarks on conjunctival plastic procedures in war injuries of the cornea. *Viestnik Oft.*, 1943, v. 22, pt. 3, p. 11.

The author disparages the use of the Kuhnt conjunctival flap in corneal injuries, preferring corneal sutures, which in his experience result in more accurately coapted edges, and better protection of the uvea. The conjunctival flap is suitable for extensive scleral and corneoscleral wounds with prolapse of uveal tissue. Gaping scleral wounds should be sutured. Ray K. Daily.

Krasnov, M. L. Clinical evaluation of hand magnets made of iron, nickel, and aluminum alloy. *Viestnik Oft.*, 1943, v. 22, pt. 3, p. 15.

On the basis of experience in one hundred cases, the author concludes that the nonelectric hand-magnet is inadequate for magnet extraction of intraocular foreign bodies, and is inferior to the electromagnet. He believes that a giant magnet is an essential equipment of an ophthalmologist attempting magnet extraction. Ray K. Daily.

Krol, A. G. A case of traumatic retinal angiopathy with recovery, fol-

lowing compression of the chest. *Viestnik Oft.*, 1943, v. 22, pt. 3, p. 27.

During explosion of an aerial bomb, a soldier suffered a blow on the chest and arm and a fracture of the left clavicle. He remained unconscious for a day. Three days after the injury he noticed impairment of vision. The eyes were examined 17 days later. In the left fundus were several edematous areas with small hemorrhages, similar to the type described by Purtscher in skull injuries. The eye recovered. The author suggests that ocular examination be made in all cases of chest injury.

Ray K. Daily.

Lijó Pavía, J. Blood disc of the cornea. *Rev. Oto-Neuro-Oft.*, 1944, v. 19, March-April, pp. 41-52.

Blood staining is an infrequent complication of contused and penetrating wounds of the cornea. It was first reported in the literature in 1509. The author reports the case history of an 8-year-old girl who received a severe direct blow to her left eye resulting in "hemophthalmos." After absorption of the blood a hematic disc was observed in the center of the cornea, extending beyond the pupillary space. The disc was reddish with a dark border. Biomicroscopic study and color photography placed the disc in Descemet's membrane and the parenchyma. Diminution in size and density of this opacity was achieved by phototherapy, using red-free light.

In his discussion the author differentiates between corneal contusion and luxation of the lens into the anterior chamber, the former being associated with corneal hyposensitivity, oscillating intraocular tension, and blood-staining of the cornea. The blood stain usually lasts months or even years.

Edward Saskin.

Ochapovskaja, D. **Hemotherapy in burns of the eyes and keratitis.** *Viestnik Oft.*, 1943, v. 22, pt. 3, p. 45.

Ochapovskaja is very enthusiastic about her method of therapy, the principal feature of which is the frequent instillation into the conjunctival sac of the patient's defibrinated blood; the cornea is thus nourished by plasma, and is provided with oxygen by the erythrocytes. In addition the blood exerts a favorable action by its content of numerous immune bodies and ferments, and it restores the normal pH disturbed by the burn. Immediately after the burn the eyeball is irrigated profusely to eliminate whatever of the offending chemical is left, and necrotic tissue is curetted away. Hemotherapy is instituted immediately, and fine adhesions between the eyeball and the lids are separated twice daily to prevent synechia. Under this régime the corneal epithelium regenerates in from two to six days. Ray K. Daily.

Pendergast, J. J. **Routine eye-treatment technique.** *Industrial Medicine*, 1944, v. 13, Aug., p. 604.

The author describes the standard ophthalmic procedure developed in the various plants of the Chrysler Corporation. Great care is taken for sterile action. Not only do nurses remove superficial foreign bodies with a tooth-pick applicator but as a war-time measure they remove embedded foreign bodies with a spud. Acid and alkali burns are to be washed with a copious amount of saline solution. If the cornea stains with fluorescein the patient must be seen by an oculist. Flash burns are treated with pontocaine and adrenalin. R. Grunfeld.

Rabinowicz, W. G. **Military plastic surgery in ophthalmology.** *Viestnik Ophth.*, 1943, v. 22, pt. 3, p. 3.

The variety of injuries about the orbit requires a versatility and individualization in surgery needed in no other region. The qualifications of an ophthalmologist doing plastic surgery are initiative, imagination, creativeness, ability to deviate from a previously prepared plan, and improvisation. He should be thoroughly acquainted with the anatomy and physiology of his surgical field. He should have a meticulously prepared plan of operative procedure, and he should be able to visualize the desired surgical result. He should choose the simplest procedure which will attain the desired objective within the shortest possible time, and which will insure restoration of anatomic form and function; and which, in case of failure, will not make further operative interference difficult by excessive destruction of tissue. He should possess a sense of form and be somewhat of an artist.

The author uses pedicle flaps and free transplants. The plastic procedures used are principally those of Imre. (Illustrations.) Ray K. Daily.

Sherman, A. R. **The application of Guist's localizing instrument in the extraction of intraocular foreign bodies by the posterior route.** *Amer. Jour. Ophth.*, 1944, v. 27, Oct., p. 1149. (1 figure.)

Siegel, Ralph. **Buccal mucous membrane grafts in treatment of burns of the eye.** *Arch. of Ophth.*, 1944, v. 32, Aug., pp. 104-108.

The treatment of severe chemical burns in eight patients is described. Seven of the patients were Negroes. In the order of their severity, the agents causing the burns in this series of cases were lye, gasoline, sulphuric acid, and lime. Five of the patients were treated

by prompt mucous-membrane grafts to the bulbar conjunctiva. The end results illustrate the value of the grafting. The author states that grafting should be performed in cases of burns of the eye of the following types: (1) direct burn of the cornea with a perilimbal circulation; (2) direct burn of the cornea with a perilimbal circulation of questionable integrity; (3) burn of the bulb with local destruction of the perilimbal circulation but unaccompanied by corneal involvement.

Immediate grafting stimulates vascularization, which helps restore corneal nutrition, with early return of functional power. This procedure also prevents the formation of scar tissue with symblepharon. If grafting is done too late or is omitted, local anoxemia leads to infiltration of the cornea, with leukoma and other sequelae. A porcelain-white sclera after a burn offers a grave prognosis unless grafting is promptly done. Even so, the damage may be so great that the eye goes on to corneal perforation. Except in those cases where the perilimbal circulation is totally destroyed, early grafting not only shortens the course of the healing process but offers a better prognosis. The technique of the operative procedure is given. (8 color photographs, references.) John C. Long.

Smelser, G. K., and Ozanics, V. **Effect of chemotherapeutic agents on cell division and healing of corneal burns and abrasions in the rat.** *Amer. Jour. Ophth.*, 1944, v. 27, Oct., pp. 1063-1072. (6 figures, references.)

Sobol, I. M. **War injuries of the nasal sinuses and their treatment.** *Viestnik Oft.*, 1943, v. 22, pt. 3, p. 28.

Injuries of the nasal sinuses are frequent and may be accompanied by

various ocular complications. Constriction in the visual field or a disturbance in color vision may be overlooked. More frequently, there is edema about the orbit accompanied by displacement of the eyeball forward or forward and outward, rapid loss of vision, headache, and septic temperature. The diagnosis of involvement of the sphenoid sinuses is difficult even with detailed roentgenographic study. The author's material shows that frequently the dominating clinical factor is not the trauma to the sphenoid sinuses but the character and extent of the secondary inflammatory phenomena, and it is these symptoms which determine the type of treatment. In firearm injuries of face and orbit the possibility of injury to the sinuses should be kept in mind, and roentgenograms taken in several positions are obligatory. Treatment has to be individualized, depending on the symptoms. Only fundus changes, extension of inflammatory phenomena in the soft orbital tissues, and meningeal symptoms should be considered indications for early operative interference.

Ray K. Daily.

Spaeth, E. B. **Removal of metallic foreign bodies from the eyeball and from the orbit.** *Proc. Interstate Postgrad. Med. Assoc. North America*, 1943, p. 52.

The eye must have retained some degree of vision if one is to attempt to remove an intraocular foreign body. The iris and the ciliary body must not be too severely damaged. When in doubt it is a wise rule to enucleate. X-ray localization is discussed, including in borderline cases the injection of air into Tenon's capsule to decide whether the foreign body is intraocular. The author discusses the choice of cases for giant magnet and hand

magnet respectively; and extraction behind the equator, with avoidance of vortex veins and followed by scleral suture. In cases of nonmagnetic foreign body, radiopaque landmarks permit flap sclerotomy and extraction. When the vitreous is clear the endoscope and specially shaped forceps for grasping the foreign body may be resorted to. In other cases the biplane fluoroscope technique has to be used.

R. Grunfeld.

Trevor-Roper, P. D. **The late results of removal of intraocular foreign bodies with the magnet.** *Brit. Jour. Ophth.*, 1944, v. 28, July, pp. 361-365.

A review of 154 cases in which a magnetic foreign body was successfully removed from the eye is given. The cases were treated at Moorfields Hospital during the first four years of the war. In only two cases was the posterior route used. One eye became shrunken and sclerotic and the other required enucleation. Removal through the scleral wound of entry was done in two cases. In both of these vision was reduced, one from a localized cataract and the other from macular striae. In the remaining 150 cases, the anterior route was employed.

Two thirds of the cases without lens injury retained good vision. The lens was injured in two thirds of the cases, but in 14 percent of these the cataract was localized enough to allow reading vision. Delay in removing the foreign body was shown to be of little consequence. Corneal wounds had a better prognosis than limbal or scleral wounds in the ciliary region. Cases without uveal damage showed a much smaller reduction of vision than cases complicated by iris or ciliary prolapse.

The strengths of the magnetic fields from various magnet tips have been

estimated and are given in tabular form.
Edna M. Reynolds.

Tumarkina, M. **Late result of a severe ocular injury.** *Viestnik Oft.*, 1943, v. 22, pt. 3, p. 46.

A student had his only eye injured by a powder explosion. When he arrived at the Helmholtz Hospital three weeks later, there was powder embedded in his lids, cornea, and conjunctiva. There was an opacity in the lens, and the vitreous was cloudy. Light projection was defective. Repeated examinations revealed dense vitreous opacities, which in places appeared as yellow membranes. The patient was deeply disturbed emotionally by the prospect of blindness, and after a month in the hospital he left with good light projection except nasally, where it was doubtful. His family was given a poor prognosis. The patient, however, began to improve, and within three years his visual acuity rose to 0.5, as the vitreous became clearer. As the fundus became visible a large yellowish-white focus surrounded by pigment was seen in the upper inner periphery; from this focus fine membranes extended into the vitreous. Such a recovery in an apparently hopeless case, while very rare, should nevertheless make us cautious in giving a poor prognosis even in grave cases.

SYSTEMIC DISEASES AND PARASITES

Maggi Zavalia, J., Zurbriggen, M. B., and Russo, O. **Ophthalmoplegic form of myasthenia gravis.** *Anales Argentinos de Oft.*, 1943, v. 4, Oct.-Nov.-Dec., pp. 143-151. (See Section 14, Eyelids and lacrimal apparatus.)

Pacheco-Luna, R. **Guatemalan onchocercosis.** *Ophth. Ibero Amer.*, 1944, v. 5, no. 4, pp. 345-347 (in Portuguese); pp. 347-350 (in English).

The disease, discovered in Guatemala in 1915 by Robles, is endemic in the rich coffee-bearing zones of the Western slope of the Guatemalan Andes, and in neighboring parts of Mexico. The filaria lives inside of fibrous tumors, which may reach the size of a dove's egg. The microfilarias emigrate outside the tumors.

Transmission of the organism is effected by means of flies of the genus *Simulides*. The number of persons attacked in Guatemala is estimated at 20,000, 2 percent of the inhabitants of the endemic zones being blind. The onset of ocular invasion is announced by intense photophobia, blepharospasm, and a sense of foreign body. There is no medicinal specific. Simple extirpation of the tumors is the principal treatment, but it has no effect on the microfilarias, which continue to live for an appreciable length of time.

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Awerbach, M. I. **The first twenty-five years of Soviet ophthalmology.** *Viestnik Oft.*, 1942, v. 21, pt. 6, p. 3.

In this article the dean of Russian ophthalmologists reviews the advances in ophthalmology during the last 25 years, and the contributions of Russian ophthalmologists. Outstanding is the development of synthetic substitutes for cocaine, which practically eliminated general anesthesia in ophthalmic surgery in adults. Corneal transplantation has become effective and feasible

since the utilization of preserved cadaver cornea was introduced by Filatov. The six thousand dacryocystorhinostomies performed at the Helmholtz Institute demonstrate that there are no contraindications to this operation. Extirpation of the lacrimal sac leaves a soldier disabled for service, while dacryocystorhinostomy permits him to return to active duty. Present investigations are concentrated in the field of plastic surgery on the lids and adjacent structures. The war did not interrupt the program of Soviet ophthalmology, but it directed research into the field of prophylaxis and treatment of war injuries. Ray K. Daily.

Crisp, W. H. **Pitfalls of the general physician in ocular diagnosis.** *Rocky Mountain Med. Jour.*, 1944, v. 41, Sept., pp. 626-633.

The author decries the attitude of some general practitioners who believe that they should not or could not learn more about the eye than they already know, and the attitude of others who keep too long a case which ought to be sent to an ophthalmologist. Every physician should know something about the anatomy and physiology of the eye, and about the principles of refraction. He should be familiar with simple methods of eye examination, for instance oblique illumination and taking tension with the fingers; and also with the use of the ophthalmoscope. He should be able to differentiate a normal from a pathologic fundus picture, and between iritis and glaucoma. He should know that marked optical defects may cause cross eye, and that this may be commonly overcome in earlier life by corrective lenses. The general physician can get this information by careful

reading and by diligent attendance at an eye clinic. R. Grunfeld.

Gradle, H. S. *The Pan-American Congress of Ophthalmology*. *Ophth. Ibero Amer.*, 1944, v. 5, no. 4, pp. 350-364.

This, translated into Portuguese, is the material which was published in English in the *Transactions of the American Academy of Ophthalmology and Otolaryngology*, 1943, October, p. 35.

Pérez Porcel, Enrique. *Trachoma in Bolivia*. *Arch. de Oft. de Buenos Aires*, 1942, v. 17, Oct., p. 605.

Bolivia is fortunate in having no trachoma problem. The rare cases observed are found in immigrants, and the native population is free from this scourge, in spite of the poverty, ignorance of elementary hygienic practices, and undernourishment of the lower classes. Analyzing the factors which make the country trachoma-free, the author discusses, among others, the following: small foreign immigration in comparison with the countries on the seaboard; inland geographic situation, with reduced population and few means of communication; population centers situated at an altitude of over 2,500 meters above sea level, with the unquestionably beneficial influence of climatic conditions. Plinio Montalván.

Post, L. T., and Slaughter, H. C. *National ophthalmological societies in the United States*. *Amer. Jour. Ophth.*, 1944, v. 27, Nov., pp. 1225-1228.

Savvaitov, A. C. *Ophthalmic services during the last twenty-five years*. *Viestnik Ophth.*, 1942, v. 21, pt. 6, p. 17.

Before the Soviet Revolution, Russia headed the list of European countries in the percentage of blindness. It had about three hundred ophthalmologists living mostly in large cities, and a total of two thousand ophthalmic beds. It had no public-health service. In 1918 the newly organized Public Health Service prepared a program of care and prophylaxis. In 1920 the ophthalmic division of the Public Health Service developed its program. As a result the number of ophthalmic beds today exceeds eight thousand, and the number of ophthalmologists exceeds two thousand. The number of graduate ophthalmic clinics increased from 11 to 35. Eleven trachoma dispensaries were opened, and almost eight thousand rural clinics and thirty-five hundred trachoma stations were established. Six eye institutes and six trachoma institutes were built, and large ophthalmic sections were opened in all large hospitals. The Helmholtz Institute in Moscow is pursuing research in retinal detachment, diasceral extraction of foreign bodies, and dacryocystorhinostomy. The Institute of Experimental Ophthalmology was devoted chiefly to corneal transplantation. The Ukraine Institute is investigating color vision and glaucoma, and the construction of ophthalmic apparatus. The prophylactic section issued numbers of leaflets, placards, exhibitions, and films for use in schools and industries and on farms. As a result the incidence of trachoma fell significantly. Ophthalmia neonatorum diminished, and blindness from smallpox was eliminated. Syphilis of the eyes is becoming rare, and complications of infectious diseases of childhood are becoming fewer. When Russia was attacked by Germany in 1941, the ophthalmic efforts were diverted

toward organization of an efficient ophthalmic service at all points of military evacuation, provision of services for evacuated civil populations, and the management of epidemics, particularly among children deprived of vitamins through confiscation of all dairy products by the Germans. Ray K. Daily.

Savvaitov, A. C. **The struggle against trachoma for the last twenty-five years.** *Viestnik Oft.*, 1942, v. 21, pt. 6, p. 22.

In Czarist Russia trachoma was very prevalent, especially among the rural population and particularly among foreigners, who were treated as colonials and had no provision for education, culture, sanitation, or medical services. The enfranchisement of foreigners, as well as of women, came with the Social Revolution. During the first years after the Revolution all medical services were attached to the Red Army. In 1922 the Trachoma Institute was opened at Kazan, as a part of the program in the struggle with trachoma. This struggle was carried on through a network of trachoma stations reaching into all trachoma areas, and through the training of specialized personnel. The program was interrupted by the war, but is to be resumed at its conclusion. Ray K. Daily.

Sená, J. A. **Evaluation of workmen's disability from partial loss of vision of one eye.** *Arch. de Oft. de Buenos Aires*, 1942, v. 17, Nov., p. 697.

The evaluation of disability from partial loss of vision of one eye must be proportionate to the visual loss sustained. The notations for visual acuity do not constitute fractions of vision. Applying to the Argentine workmen's compensation laws the percentages of

visual efficiency derived from the experimental, clinical, and mathematic researches of Snell and Sterling, approved by the American Medical Association, values are obtained which correspond very closely to those arrived at by the author to determine the disability from partial loss of vision of one eye when the other eye is normal. (Tables.) Plinio Montalván.

Sorsby, Arnold. **Trachoma in London: the end of a chapter.** *Brit. Med. Jour.*, 1944, Aug. 12, p. 220.

In May, 1944, the last five remaining children in the trachoma block at White Oak Hospital were discharged and the block closed down. Formerly, poor hygienic conditions and rudimentary medical facilities made trachoma and other infections endemic in Poor Law institutions. The need for effective isolation and treatment was pressed upon the authorities, with the result that two ophthalmic hospital-schools were erected. The other hospital school became superfluous in 1918. The numbers of admissions to the White Oak Hospital were as follows: In 1903, 292; between 1904 and 1913, a yearly average of 112; during the next decade, 29; the following decade, 34; and in the last decade an average of 13 yearly admissions.

Trachoma is still not infrequent in London and remains a potential source of epidemic. Early and persistent treatment is essential. As indicative of what can be achieved by systematized and persistent effort the experience at Glasgow is quoted. Notification is compulsory. Systematic treatment in the trachoma clinic and examination of contacts are carried out, and provision is made for hospitalization of adults and children who need it. The number of

new cases in Glasgow in 1915 was 112; in 1925, 41; in 1935, 18; and in 1943, 3.

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Haden, H. C. Concerning the relations of the developing optic nerve to the recessus opticus and the hypophysis in young fetuses: a study of seven human fetuses 4 mm. to 40 mm. inclusive. *Amer. Jour. Ophth.*, 1944, v. 27, Oct., part 2, pp. 1-44. (41 illustrations, references.)

Semeraro, Edmundo. Contribution to anatomic study of the eyeball. *Rev. Brasileira de Oft.*, 1943, v. 1, June, pp. 209-212.

The author describes the variations which he has encountered post mortem, in the structure of Tenon's capsule. Sometimes there are strong adhesions of the capsule to the fatty tissue and the ocular muscles. Sometimes such adhesions are absent. Sometimes Tenon's capsule seems to have undergone complete atrophy and disappearance. Some brief comments are offered as to the effect of these variations on surgical principle. (2 illustrations.)

W. H. Crisp.

Van Harreveld, A. Oxygen consumption of degenerated optic nerves. *Proc. Soc. Exper. Biol. and Med.*, 1944, v. 56, June, p. 192.

The author takes issue with a report of increase in oxygen consumption of degenerated human optic nerves (Michail and Benetato, *Soc. Biol.*; Paris, 1936, v. 121, p. 267.)

To support his contention the author severed the optic nerves of one eye in

each of six cats, and six months later removed the nerves and compared the oxygen consumption. In two cases the degenerated nerve had slightly higher metabolism, in the other four it was lower, the average favoring the normal nerves. It is suggested that the previous observations may have been in error because the nerves were minced, thereby reducing their oxygen utilization. Benjamin Milder.

Vidal, F., and Malbrán, J. L. Arrangement of the myelin fibers in the chiasm of the cat. *Arch. de Oft. de Buenos Aires*, 1942, v. 17, Nov., p. 684.

Of a series of 20 cats, one or both eyes were enucleated. In some and retinal microlesions were produced in others. The cats were allowed to live from nine days to ten months. The chiasms were studied following cresyl-violet, Weil, and Marchi techniques. From this experimental work it can be stated that in the cat no retinal fiber ends in the hypothalamus. The number of crossed fibers in the chiasm is larger than of uncrossed; the former occupy the rostral portion of this structure and the external border of its posterior half, while the latter run along the lateral borders of the anterior half of the chiasm and the ventral portion of the posterior half, where they mingle with the crossed fibers. The septohypothalamic fibers are found in the rostral and dorsal portions of the chiasm. The fibers of the ventral supraoptic commissure or commissure of Gudden invade the posterior third of the chiasm, forming its posterior border. The fibers of the ventral geniculate body are situated in the caudal and ventral portions of the commissure of Gudden. The fibers of the supraoptic dorsal commissure or commissure of Meynert

occupy the rostral portion of the medial hypothalamus and the fibers of the supraoptic dorsal commissure or commissure of Ganser are situated in the dorsal part of the medial hypothalamus. (Photomicrographs, references.)
Plinio Montalván.

Vidal, F., and Malbrán, J. L. **Arrangement of the superior homolateral optic fibers in the cat.** *Arch. de Oft. de Buenos Aires*, 1942, v. 17, Oct., p. 626.

In this experimental work the authors employ the same technical procedure described in a previous paper (*Amer. Jour. Ophth.*, 1944, v. 27, p.

1058) concerning the inferior peripheral homolateral fibers in the cat, producing first a retinal microlesion and studying the direction and extent of the ensuing degenerative changes throughout the primary optic tract. From the present work they show that the superior homolateral fibers have a superior or dorsal arrangement in relation to the inferior peripheral homolateral fibers. They also prove that the fibers first run on the external aspect of the tract, taking a medial position when they reach the dorsal geniculate body. (Photomicrographs.)

News items should reach the editor by the twelfth of the month.

DEATHS

Dr. Joseph T. Auwers, Grand Rapids, Michigan, died September 12, 1944, aged 59 years.

Mr. William Bausch, Bausch and Lomb Optical Company, Rochester, New York, died October 19, 1944, aged 83 years.

Dr. J. A. Biever, Mount Joy, Pennsylvania, died August 27, 1944, aged 86 years.

Dr. Howard Black, Palo Alto, California, died September 21, 1944, aged 70 years.

Dr. William K. Campbell, Long Branch, New Jersey, died September 21, 1944, aged 65 years.

Dr. Charles H. Crain, Evanston, Illinois, died September 29, 1944, aged 89 years.

Dr. Richard S. Crichlow, New Orleans, Louisiana, died September 18, 1944, aged 62 years.

Dr. William E. Joiner, Seattle, Washington, died August 7, 1944, aged 74 years.

Dr. Robert H. Kistler, Lansford, Pennsylvania, died October 4, 1944, aged 55 years.

Dr. Arnaud J. LaPierre, Norwich, Connecticut, died July 12, 1944, aged 59 years.

Dr. Archibald C. Lewis, Memphis, Tennessee, died September 18, 1944, aged 67 years.

Dr. Daniel J. Maloney, Waterbury, Connecticut, died August 4, 1944, aged 77 years.

Dr. Benjamin F. Matheny, Parsons, West Virginia, died September 8, 1944, aged 65 years.

Dr. Hugh S. McKeown, New York, New York, died September 14, 1944, aged 49 years.

Dr. Elmer E. Owen, Batavia, New York, died August 2, 1944, aged 62 years.

Dr. Joseph W. Robinson, Lisbon, Ohio, died September 21, 1944, aged 50 years.

Dr. Charles M. Rosenthal, Brooklyn, New York, died September 1, 1944, aged 35 years.

Dr. Olaf H. Rystad, Grand Forks, North Dakota, died August 16, 1944, aged 68 years.

Dr. Frederick A. Smith, Troy, New York, died August 7, 1944, aged 76 years.

Dr. Henry D. Smith, Sanford, Florida, died August 12, 1944, aged 54 years.

Dr. Louie L. Steiner, Danville, Illinois, died August 17, 1944, aged 65 years.

Dr. Harry J. Stewart, San Diego, California, died October 31, 1944, aged 76 years.

Dr. James Thorington, Philadelphia, Pennsylvania, died October 27, 1944, aged 86 years.

Dr. William F. Waggoner, Carrollton, Illinois, died July 14, 1944, aged 77 years.

Dr. Edwin D. Watkins, Memphis, Tennessee, died July 31, 1944, aged 62 years.

Dr. Cephas J. Wells, Bartlesville, Oklahoma, died September 9, 1944, aged 79 years.

Dr. John E. Virden, New York, New York, died August 30, 1944, aged 81 years.

MISCELLANEOUS

A six-month course for orthoptic technicians will be given by The George Washington University School of Medicine, Washington, D.C., beginning February 5, 1945. Trainees must be sponsored by certified ophthalmologists. The fee for the course is \$250.00. For further details write to Dr. Ernest Sheppard, School for Orthoptic Training, The George Washington University School of Medicine, 1335 H Street, N.W., Washington 5, D.C.

An orthoptic clinic has been established at the James Whitcomb Riley Hospital for Children at Indianapolis to provide special training for children who have difficulty in eye focusing and to supplement surgery for correction of strabismus.

SOCIETIES

The Washington, D.C., Ophthalmological Society elected the following officers for the 1944-1945 season: Dr. Harold R. Downey, president; Dr. John R. Lloyd, vice-president; and Dr. Richard W. Wilkinson, secretary-treasurer.

The officers of the Milwaukee Oto-Ophthalmic Society for 1944-1945 are: Dr. Leon H. Guerin, president; Dr. Ralph T. Rank, vice-president; and Dr. Frank G. Treskow, secretary-treasurer.

At the meeting of the Eastern Pennsylvania Association of Eye, Ear, Nose, and Throat Physicians in Wilkes-Barre on May 10, 1944, it was unanimously decided to change the name of that organization to the Pennsylvania Academy of Ophthalmology and Otolaryngology.

The following officers were elected: Dr. Lewis T. Buckman, president; Dr. Roy Deck, first vice-president; Dr. M. M. Rosenberg, second vice-president; Dr. Daniel S. DeStio, third vice-president; Lieut. Comdr. Sterling F. Mengel (MC) U.S.N. (on active duty), secretary; Dr. Paul C. Craig, secretary pro tem; and Dr. James J. Monahan, treasurer.

The scientific program consisted of the following papers: "Dentigerous cyst" by Dr.

Thomas R. Gagon; "Anatomy of middle ear and mastoid" by Dr. Horace J. Williams; "Neuropsychiatric aspects of ophthalmology and otolaryngology" by Dr. L. Vosburgh Lyons; "Ocular infections" by Dr. Isadore Givner; and "Sinusitis" by Dr. Blake F. Donaldson.

At the forty-ninth annual meeting of the Seaboard Medical Association of Virginia and North Carolina, December 5th to 7th, Dr. Antonio A. Burke, Norfolk, Virginia, presented a paper on "Glaucoma with especial relation to early treatment."

The second annual clinical conference of the Chicago Medical Society will be held from February 27th to March 1st at the Palmer House in Chicago. Dr. Peter C. Kronfeld, Chicago, will be among the guest speakers.

At the meeting of the Washington, D.C., Ophthalmological Society on November 6, 1944, Dr. Frank Walsh of Baltimore, the guest speaker, discussed "Some syphilitic involvements of the optic nerve." Dr. James S. Dryden reported a case, entitled "Glaucoma, acute, secondary to luxated intumescent lens." The following case presentations were made: "Detachment of the retina" by Dr. Sterling Bockoven; "Fractured skull with bitemporal hemianopia" by Dr. Joseph Dessoff; "A case of tuberculous choroiditis" by Dr. Thomas A. Egan; "An ocular myasthenia gravis" by Dr. Dorothy B. Holmes; "Complete central blindness of unknown cause" by Dr. Thomas R. Rees; and "Tear in Descemet's membrane" and "Gonorrheal conjunctivitis in adult treated with penicillin" by Dr. Roy A. Stewart.

At the regular monthly meeting of the Milwaukee Oto-Ophthalmic Society, held jointly with the Milwaukee Academy of Medicine on December 19th, Dr. James Watson White, New York, conducted an all-day course on "Ocular muscles."

The Dallas Southern Clinical Society will hold its fifteenth annual Spring Clinical Conference, March 19-22, 1945. Among the guest speakers will be Dr. Edmund B. Spaeth, Philadelphia.

PERSONALS

Major Middleton E. Randolph (MC), Chief of the Ophthalmology Branch, Surgical Consultants Division, Office of the Surgeon General, has been assigned liaison officer with the Committee on Sensory Devices, Office of Scientific Research and Development, it has been recently announced.

The Cleveland Community Fund presented Drs. Charles I. Thomas and William E. Bruner with the distinguished service award for outstanding work in the field of sight restoration.

On November 24th, the Saint Louis Ophthalmic Society gave a dinner in honor of two of its members, Dr. John Green and Dr. Lawrence T. Post, past presidents, respectively, of the American Ophthalmological Society and the American Academy of Ophthalmology and Otolaryngology. About 50 members and guests were present. Dr. Frederick E. Woodruff read a paper on, "The history of ophthalmology in Saint Louis."

*Pontocaine
Hydrochloride*

in

OPHTHALMOLOGY

and in

RHINOLARYNGOLOGY

*Surface Anesthetic
with Prolonged Effect*

Dependable anesthesia
of the mucous membranes

is readily obtained by the topical application of Pontocaine hydrochloride. This widely used agent acts quickly, penetrates deeply, and gives prolonged anesthesia. A variety of operative and nonoperative procedures on the eye, nose and throat may be successfully carried out with small quantities of relatively weak solutions.

HOW SUPPLIED: For surface anesthesia in ophthalmology: 0.5 per cent solution in bottles of $\frac{1}{2}$ oz. and 2 oz.

For surface anesthesia in rhinolaryngology: 2 per cent solution in bottles of 1 oz. and 4 oz.

*Not
a Narcotic*

FIG. 1 (FRALICK), RUBEOSIS IRIDIS DIABETICA

RUBEOSIS IRIDIS DIABETICA*

F. BRUCE FRALICK, M.D.

Ann Arbor, Michigan

Rubeosis iridis diabetica is the term given by Salus¹ to signify the presence of new-formed blood vessels in the sphincter region of the anterior surface of the iris. He rightly believed that he was dealing with a syndrome not previously described, since the condition was observed bilaterally in three diabetic patients, all eventually showing glaucoma. Thirty-two case reports, including those of his three patients, showing rubeosis of the iris in association with diabetes have appeared in the literature.

Salus emphasized that "rubeosis iridis is not rare, as it is frequently seen in its minor degrees but only occasionally in a well-defined manner." He called it "a second diabetic iris change," the first being black aqueous from hydroptic degeneration of the posterior iris epithelium. Salus's original description bears repetition despite the accumulation of additional information concerning rubeosis iridis since his communication was published:

"The normal iris is covered by radially arranged groups of light-red capillary nets which are placed closely together. They are connected by thicker, shorter, and horizontally running small vessels. These groups of vessels end in the vicinity of the pupil at the pigment margin without extending over it. They terminate at the ciliary end of the pupillary region so that their utmost ends cover it but they do not extend over its margin to any considerable degree. Thus, the whole pupillary part of the iris is covered by a dense net of chiefly radially running capillaries; it acquires a rose-red tinge,

particularly striking in a blue iris, which ends suddenly at the ciliary border. Starting at the capillary net, there are more or less numerous larger light-red vessels in irregular curves spreading over the iris and disappearing in the angle of the anterior chamber. They collapse if one presses upon the corresponding part of the limbus and are filled again from the side of the iris after pressure is discontinued."

At first, Salus was under the impression that the iris condition which he described was somehow caused by glaucoma, probably through venous stasis. Waite and Beetham² were of the opinion that rubeosis was a sequel to hemorrhagic glaucoma, not uncommon in diabetics, rather than a sequel to diabetes itself, in their excellent investigation of ocular complications found in 2,002 consecutive diabetic patients. Salus, however, after observing rubeosis iridis in two eyes not manifesting glaucoma for two and five years, respectively, reversed his impressions. This observation has been substantiated by Gil,³ v. Sallmann,⁴ Motolese,⁵ Gallino,⁶ and Fehrmann.⁷ Thus, it may quite definitely be accepted that it is the vascular proliferation on the iris that eventually leads to glaucoma. Credit should therefore also be given to Salus for first suggesting that the capillary changes of the iris precipitated the glaucoma and that differentiation be made between the usual primary glaucoma and the type manifesting rubeosis iridis in the eye of diabetics.

Following Salus's observations, but without adding significantly to the knowl-

* Candidate's thesis accepted by the American Ophthalmological Society, June, 1944.

edge of rubeosis iridis, Axenfeld,⁸ Arruga,⁹ Waldstein,¹⁰ Lawrence and Levy,¹¹ Gallino,⁶ and Motolese⁵ reported similar eye conditions. The gonioscopic and pathologic findings of an eye showing rubeosis iridis and glaucoma in a diabetic individual was first described by Kurz¹² in 1937. Salus's conception of the cause of glaucoma in these eyes was confirmed and further elaborated by these findings.

By gonioscopic examination Kurz found that the chamber angle was bridged here and there by peripheral synechiae of varying width, and that the iris surface in the region of the anterior synechiae were elevated, giving the iris "the appearance of corrugated iron." He described large newly developed vessels on the iris ridges. Clumps or knots of fine vessels quite similar to, but not tending to be so diffusely disposed as those seen in the sphincter region, were noted in the valleys between the ridges. In this instance, Schlemm's canal was filled with blood and seemed to be directly connected with the vascular proliferation in the region of the anterior synechiae. Kurz described innumerable delicate vascular loops forming nets which run from the surface of the iris up over and partially covering the corneoscleral trabeculum. These changes advanced as time elapsed, and caused the crest of the iris waves to become higher and broader until the entire circumference of the chamber was finally filled with the adhesion.

In another significant observation in connection with rubeosis iridis, Kurz found that the vascular net in a rubeotic eye disappeared with the development of iris atrophy. Therefore, as these eyes go into absolute glaucoma they might not show evidence of a previously existing rubeosis iridis. This fact was beautifully demonstrated in two patients presented by Motolese. Both of his patients had one absolute glaucomatous eye without rube-

osis, and both had rubeosis but as yet no glaucoma in the other eye.

The slitlamp and gonioscopic findings were confirmed by Kurz in pathologic studies of a rubeotic eye. The changes in the iris consisted of extensive proliferation of the vessels in the sphincter and ciliary regions accompanied by extensive extravasations. No similar vessel proliferations were noted in the ciliary body. It is hard to conjecture just why the anterior surface of the iris should be selected as the site of this peculiar vessel proliferation in diabetic and nondiabetic rubeosis. It has not as yet been determined whether there are differences in the aqueous of diabetics with and without rubeosis. Rubeotic eyes examined pathologically have not shown significant vascular changes in the ciliary processes to confirm the theory that degenerative vascular changes in the presence of diabetes might so alter the metabolic constituents of the aqueous as to bring about vascular proliferation on the iris surface in the regions of the greater and lesser arterial circles. Hemorrhagic retinopathy and a tendency to vascular proliferations in and on the retina and optic nerve were noted by Kurz,¹² and later by Favaloro,¹³ Fehrmann,⁷ and Sugar¹⁴ in pathologic examinations of rubeotic eyes.

Two cases presenting the clinical picture of rubeosis in the absence of diabetes have been reported by Fehrmann.⁷ He attempted to establish a differential diagnosis that would enable one to distinguish the two entities, but the clinical differences were slight and the pathologic picture of both was that of vascular and circulatory changes. In the comparative clinical and pathologic studies of the diabetic and nondiabetic rubeotic eyes he pointed out essential differences sufficient for him to place them as entities. He found the nondiabetic rubeotic iris vessels to be larger and to run in a layer

of connective tissue attached to the anterior limiting layer and at times to surpass the pupillary margin. The latter has never been observed in rubeosis. The iris stroma in nondiabetic patients contains connective tissue which so far has not been observed pathologically in rubeosis. Nondiabetic glaucomatous scar tissue in the iris angle consists chiefly of dense tissue whereas in rubeosis synechiae the capillaries predominate in the adhesion and extend to the angle. Rubeosis is often accompanied by new-vessel formation in and on the papilla and in the retina underneath the limitans interna.

A study of the reported cases reveals that rubeosis iridis occurs in cases of severe diabetics in the young as well as in those observed in older cases of mild diabetes which have not been well controlled. For some time we have been impressed by the fact that the metabolic disturbances are often much more serious in the juvenile diabetic than in senile cases. We, therefore, must conclude that rubeosis does not depend entirely upon the severity of the diabetes. It is my opinion that rubeosis iridis is caused chiefly by vascular and circulatory changes, but the diabetes must be considered as an etiologic factor. If this were not true, the syndrome would be seen in nondiabetics with circulatory changes.

Other points to consider are the possible relationship between hypertension and rubeosis as mentioned by Kurz,¹² and the fact that hypertension and diabetes together in the same patient manifest a much higher percentage of vascular pathologic change than when either is alone. Hypertension and diabetes were associated in thirteen of the 32 reports of rubeosis. Patients suffering from diabetes complicated by hypertension were not significantly younger (average 59 years) than were those who had not the complication of hypertension (average 57

years). As yet, one does not see any more than a possible relationship between rubeosis iridis diabctica and arterial hypertension from the small number of cases so far reported.

The writer has seen three patients who presented the syndrome of rubeosis iridis diabctica. In addition, two others were seen whose pathologic picture did not conform to the syndrome but so closely approximated the findings that a differential diagnosis was difficult except for the absence of diabetes. These five patients are herewith presented for comparison of their clinical and pathologic manifestations.

CASE REPORTS

CASE 1. R. M., a man, 61 years old, had noted gradual failure of vision in both eyes for eight months. No inflammation nor pain was experienced until three weeks before examination, when the right eye became congested, painful, and the vision markedly decreased. He had been a known diabetic for 12 years before, but no treatment had been instituted until the past four years, when dietary and insulin treatments were started. For the past two years he had used no insulin and had not been careful with his diet so that he was occasionally not sugar free.

The *cyc examination* revealed vision, O.D. sufficient to count fingers and O.S. 2/60. The intraocular pressure (Schiotz) O.D. was 90+ and O.S. 20 mm. Hg. The right eye was markedly congested throughout. The cornea was edematous; the fundus examination was therefore impossible. The anterior chamber was of normal depth. On the blue iris surface for a width of about 1 mm. about the pupil and inside the zig-zag line there was a definite reddish flush produced by the presence of clumps of fine new-formed capillaries as seen by the slitlamp. These

Fig. 2

Fig. 3

Fig. 4

Fig. 5

Fig. 6

Fig. 7

Fig. 8

Fig. 9

tufts of capillaries were not diffusely disposed about the pupil but were patchy in their distribution. Several larger vessels, radiating from these vascular tufts, proceeded toward the iris base. These radiating vessels either disappeared behind the limbus or ended in capillary tufts on the anterior iris surface before reaching the limbal area. The peripheral capillary tufts also disappeared behind the limbus. The pupil was round, measuring 4 mm. in diameter, and was fixed to light and in accommodation. No synechiae were found. The iris stroma aside from the new-formed vessels appeared normal. No keratic precipitates were present. Transillumination was negative for intraocular tumor.

The left eye presented a normal anterior segment. The vitreous was loaded with fine opacities. There was a subhyaloid hemorrhage below the disc. Many lipid infiltrates were noted in and about the macular area. Numerous scattered punctate retinal hemorrhages were present throughout. The retinal arterioles showed marked sclerosis and variation in caliber.

Gonioscopic examination of the right

eye showed the presence of complete anterior synechiae. The peripheral new-formed vessels on the anterior iris surface in some places extended onto the posterior surface of the cornea and in other places it did not reach the corneal surface. The large vessels seemed to disappear in the capillary tufts or iris stroma. The left eye presented normal angle markings and no new-formed vessels on the anterior iris surface peripherally.

General physical examination showed a blood pressure of 180/120; advanced generalized arteriosclerosis; and moderate cardiac enlargement with blowing apical systolic murmur.

Laboratory examinations: Blood Kahn negative. Fasting blood sugar 276 mg. percent. Urine showed 4+ albumen, 4+ sugar, many red blood cells, and waxy and granular casts.

Diagnoses. O.D., rubeosis iridis diabetica; secondary glaucoma. O.S., retinitis hemorrhagica; retinal arteriolar sclerosis. Diabetes mellitus. Arteriosclerotic and hypertensive heart disease with cardiac enlargement and nephropathy. Generalized arteriosclerosis.

Figs. 2-9 (Fralick).

Fig. 2. Case 1, right eye. Photomicrograph showing peripheral glaucomatous anterior synechia. New-formed blood vessels seen to extend from anterior iris surface to cornea at *a*.

Fig. 3. Case 1, right eye. Photomicrograph showing new-formed "rubeotic" blood vessels on anterior iris surface in scar tissue causing ectropion uveae.

Fig. 4. Case 1, right eye. Photomicrograph showing hyaline coagula associated with hemorrhagic retinopathy in the outer plexiform layers of the retina.

Fig. 5. Case 2, left eye. Photomicrograph showing typical glaucomatous anterior synechia without prominence of blood vessels in the scar. New-formed blood vessels on the anterior iris surface peripherally extend along synechia to cornea. Hydroptic degeneration of posterior pigment epithelium of iris is marked.

Fig. 6. Case 2, left eye. Photomicrograph showing new-formed blood vessels on the anterior iris surface in an inflammatory membrane which causes ectropion uveae.

Fig. 7. Case 2, right eye. Photomicrograph showing glaucomatous anterior synechia without blood vessels in the scar. At *a* is a blood vessel extending from the anterior iris surface to the cornea. Hydroptic degeneration of the posterior iris pigment epithelium is marked.

Fig. 8. Case 2, right eye. Photomicrograph showing thickening of anterior stromal tissue of iris causing ectropion uveae. New-formed blood vessels on anterior iris surface in sphincter region are conspicuous.

Fig. 9. Case 2, right eye. Photomicrograph showing organized inflammatory and hemorrhagic exudate on optic disc and retina. Exudate extends between retina and choroid.

Course. Miotics were employed and did not decrease the tension nor ocular pain. The right eye was enucleated.

Pathologic examination. O.D., Army Medical Museum accession number 73483. *Gross:* Firm eye measuring 25 by 24 by 24 mm. The cornea is clear. The eye is opened in the horizontal plane. The vessels radiating from the optic disc are prominent. The region surrounding the disc is thickened and dotted with opaque and hemorrhagic areas. The lens is opaque. *Microscopic:* Descemet's membrane is irregularly thickened at the periphery. The iris shows peripheral anterior synechiae of the typical glaucomatous type. There is no noticeable increase in the blood vessels in this scar as compared to the usual glaucomatous scar. There are some new-formed blood vessels on the peripheral anterior iris surface, which, along with scar tissue, extend forward for a short distance on the posterior surface of the cornea. There is a variable amount of iris atrophy. At some points of the pupillary margin a variable amount of ectropion uveae exists. There is a definite thickening of the stromal tissue on the anterior iris surface, indicating an inflammatory reaction in this case. There is seen a variable amount of new-formed vascularization, particularly over the sphincter muscle. Some hemorrhage is noted in the iris in the region of the anterior synechiae. There is slight hydroptic degeneration of the iris pigment epithelium. Pigment on the anterior lens capsule and a comparable loss of pigment from the posterior iris surface indicate the former site of a posterior synechia. The ciliary processes are hyalinized. There are some hyalinization of the walls of the retinal vessels and hemorrhages in the nerve fiber and outer plexiform layers. Numerous hyaline coagula are present in the outer plexiform layer, particularly in the macular region, and in this layer are

also seen lipoidal histiocytes. There is a small area of microcystic degeneration on the nasal side posteriorly. A little hemorrhage appears in the vitreous chamber. The optic disc and lamina cribrosa are slightly depressed. No new-formed vessels are seen on the surface of the retina and optic disc.

CASE 2. B. G., a woman, aged 34 years, had noted visual failure in both eyes 10 months previously, and had not been able to read after two months. One week before examination the left lids became so edematous that she could not open the eye. There was pain and inflammation of the eyeball associated with the edema. She had learned that she had diabetes and hypertension during pregnancy, 14 years before and had been treated for these since then, but had found them both difficult to control. She had noticed dyspnea on walking up one flight of stairs. She also had had convulsions during the aforementioned pregnancy.

The *eye examination* showed an uncorrected vision of O.D. 1/60, and O.S. "moving objects." The intraocular pressure (Schiotz) was O.D. 29 mm. and O.S. 90+ mm. Hg. The external examination of the right eye was normal except for the absence of the direct light pupillary reflex. The fundus showed scattered punctate retinal hemorrhages, scattered lipid retinal infiltrates centrally, and marked retinal arteriolar sclerosis.

The left eye showed edema of the cornea but no keratitic precipitates. There were no posterior synechiae. The pupil was dilated to 4 mm. and fixed, irregular in outline. Just outside the pigmented margin of the pupil the iris showed a fine network of new-formed vessels which covered the sphincter zone and gave a reddish hue to this portion of the iris. From this vascular zone on the surface of the iris several more or less straight

vessels coursed toward the base of the iris, some disappeared behind the limbus, and others were found to terminate in small capillary networks. The remainder of the iris did not appear to show signs of inflammation. The fundus examination was impossible for details because of the edematous cornea. Transillumination was negative for intraocular tumor.

Gonioscopic examination. The patient was too ill to permit study.

General physical examination revealed a blood pressure of 200/100; adenoma of the right lobe of the thyroid; and heart of borderline size with systolic murmur at the apex.

Laboratory examinations. Urine showed 4+ albumen, 2+ sugar, and amorphous casts. Blood—hemoglobin 70 percent, red blood cells 4.01, white blood cells 11,750; differential and smear normal. Blood Kahn negative. Fasting blood sugar 140 mg. percent. Blood non-protein nitrogen 53.5 mg. percent.

Diagnoses. O.S., glaucoma (acute, congestive); rubeosis iridis diabetica. O.D., retinitis hemorrhagica; glaucoma (secondary). Diabetes mellitus. Chronic glomerular nephritis. Secondary anemia. Nontoxic thyroid adenoma. Secondary hypertension.

Course. Intensive miotic therapy together with 15 mg. retrobulbar mechoyl chloride reduced the tension in the left eye to 47 mm. Hg (Schiotz), but after 24 hours the tension was again stony. The patient was extremely ill and the relatives refused the advice of enucleation of the left eye and removed the patient from the hospital. Tension in the right eye was reduced to 22 mm. (Schiotz), but it was felt that this eye also was headed for trouble. The left eye was later removed by Dr. Ray Hughes of Detroit, Michigan, and sent to the Army Medical Museum.

The right eye remained painless and

the tension normal until two months later, when the patient returned to Dr. Hughes with a tension of 10 mm. Hg (Schiotz). The pupil was dilated and immobile. Vision was 20/300. The anterior chamber was deep. The patient had no pain. There was a well-developed rubeosis iridis. The cornea was clear. Fundus examination at this time showed retinal hemorrhages and a preapillary growth of new-formed blood vessels which extended forward into the vitreous for 5 to 6 diopters. Mecholyl and prostigmin contracted the pupil to pinhead size and the tension was reduced to 50 to 55 mm. Hg (Schiotz). Under the influence of the vaso-constrictive mechoyl, the rubeotic vessels disappeared and the iris assumed its normal appearance. Corneal abrasion and ulceration together with violent uveitis developed as the result of tonometry, and the right eye was enucleated by Dr. Hughes. This eye was also sent to the Army Museum.

Pathologic examination. Army Medical Museum accession number 75587. O.S.: *Gross:* Firm eye measuring 25 by 24 by 25 mm. The cornea appears clouded. The eye is opened in the horizontal plane. The region surrounding the macula is opaque. The vessels radiating from the disc are distinctly defined. The lens is opaque. There are a few posterior synechiae at the pupillary margin. *Microscopic:* A little hemorrhage is present in the anterior chamber. There are peripheral anterior synechiae of the characteristic glaucoma type except that there are new-formed blood vessels on the anterior surface of the iris peripherally and it is possible to trace these for a short distance into the juncture between the cornea and the iris in the adhesion. The anterior surface of the iris is covered by a definite vascular membrane. The blood vessels are most numerous in the sphincter and peripheral regions of the iris. There are advanced

cystoid or hydroptic degeneration of the pigment epithelium of the iris and a low degree of ectropion uveae. Pigment on the anterior lens capsule indicates that posterior synechiae were present. Calcified drusen appear at the ora serrata. The choroid is not remarkable but the ciliary body shows considerable atrophy. The ciliary processes show hyalinization. The retina shows hemorrhages in the nerve fiber and outer plexiform layers, edema and loss of normal architecture at the macula, engorged and sclerotic vessels, and hyaline coagula around the macula. There is an area of retinal separation about the disc. On the nasal side the pigment epithelium does not extend to the disc margin, and on the temporal side all the layers of the retina extend out over the nerve. The optic disc is cupped and the lamina cribrosa is depressed.

O.D.: Gross: Soft eye measuring 23 by 23 by 22 mm. There is a small corneal ulcer slightly off center and thickening at the limbus. The eye is opened between the horizontal and vertical planes. An opaque exudate fills the anterior chamber. The lens is opaque and the vitreous is cloudy. There is a threadlike adhesion from the raised disc to the vitreous. The optic nerve is too short for cross section. *Microscopic:* The epithelial layer and Bowman's membrane are absent (some sections) over a purulent corneal ulcer. Purulent exudate fills the anterior chamber and infiltrates the iris. Hemorrhage is present in the anterior chamber and around the pupillary margin of the iris. There are peripheral anterior synechiae of the typical glaucoma type. Very few blood vessels are seen at the juncture of the iris and cornea, but there are a few on the peripheral portions of the iris central to the anterior synechiae. There is a vascular membrane on the anterior surface of the iris, vascularization of the

pupillary portion over the spinster region being the most prominent. There are ectropion uveae and marked hydroptic degeneration of the iris pigment epithelium. Pigment on the anterior lens capsule indicates that posterior synechiae were present. There are edema and hyalinization of the ciliary processes. The ciliary body and choroid are atrophic. There is a little chronic inflammatory cell infiltration in the uveal tract. The retina shows reduction of ganglion cells and atrophy, and gliosis of the nerve fiber layer. There are small serous exudates in, and microcystic degeneration of the outer plexiform layer, and rarefaction of the inner nuclear layer in the macular region. Organizing inflammatory and hemorrhagic exudate extends from the optic disc into the vitreous chamber and has proliferated both on the inner surface of the retina and between the retina and underlying choroid. An apparent vascular occlusion in the optic disc is believed to be an artifact. The lamina cribrosa is depressed and the optic nerve is atrophic. There is chronic inflammatory cell infiltration of the episclera.

CASE 3. E. H. F., a woman, 59 years old, had known for three years that she had glaucoma. The increased tension was controlled with eserine until November 8, 1941, when she had an attack of acute glaucoma in the right eye. The tension of this eye had never been controlled since. The eye had given pain more or less since this attack. The patient was under the care of her local physician for hypertension but had never known of the presence of diabetes.

The eye examination revealed a vision of O.D. light perception; and O.S. moving shadows. The intraocular pressure was O.D. 90 mm. (Schiotz) and O.S. 20 mm. Hg. Slitlamp examination

showed the right cornea to be edematous, but there was no evidence of anterior uveal disease. The iris of the right eye showed new-formed, fine blood vessels on its anterior surface. These vessels were outside the pigment border and largely confined to the sphincter area. There were a few larger radiating vessels from this marginal plexus which went to the base of the iris and disappeared behind the limbus. The pupil was slightly dilated and fixed. No fundus details were seen through the edematous cornea. Transillumination was negative for intraocular tumor.

The left eye was negative externally but the fundus examination showed scattered punctate retinal hemorrhages, moderate retinal arteriolar sclerosis, and in and about the central area were scattered lipid exudates.

Gonioscopic examination. The right eye showed complete anterior synechiae so that none of the angle markings were visible. There were clumps of new-formed vessels on the anterior iris surface peripherally which were not seen on external examination. These extended up onto the posterior surface of the cornea. The left eye showed normal angle markings with no clumps of new-formed vessels visible. There were no synechiae.

General examination. Generalized arteriosclerosis. Heart slightly enlarged. Blood pressure 185/110.

Laboratory examinations. Fasting blood sugar 170 mg. percent. Urine showed 4+ sugar and 1+ albumen.

Diagnoses. O.D., glaucoma (chronic uncompensated), rubeosis iridis diabetica. O.S., retinitis hemorrhagica, arteriosclerosis (retinal). Diabetes mellitus. Hypertension.

Course. Intensive miotics and retrobulbar mecholyl did not reduce the tension of the right eye below 75 mm. Hg

(Schiotz). The pupil was constricted and the ruby-red coloration of the iris lost due to the marked vasoconstriction of the new-formed vessels on the anterior iris surface. The right eye was enucleated by Dr. E. W. Campbell of Toledo, Ohio, and sent to the Army Medical Museum.

Pathologic examination. O.D., Army Medical Museum accession number 78450. *Gross:* Moderately firm eye coated with hemorrhage, measuring 24 by 24 by 25 mm. The cornea is opaque, the limbus is thickened. The eye is opened, presumably in the horizontal plane. The vitreous is cloudy and the lens is opaque. Numerous areas of retinal hemorrhage are noted. The sclera is thin. The optic nerve is too short for independent section. *Microscopic:* Hemorrhagic exudate extends over the cornea on one side. The corneal epithelium is thin. There is a little hemorrhagic exudate in the anterior chamber. There are peripheral anterior and marginal posterior synechiae and ectropion uveae. The anterior synechia does not entirely cover the trabecular fibers. There is no noticeable vascularity of the juncture between the iris and trabecular fibers. A vascular membrane is present on the anterior surface of the iris. The new-formed blood vessels are especially noticeable over the sphincter and peripheral portions of the iris. The iris pigment epithelium shows hydroptic degeneration of a slight degree. The ciliary processes are hyalinized. The choroid is somewhat thin, and there are occasional early excrescences on Bruch's membrane. The retina shows cystic degeneration at the ora serrata, reduction of ganglion cells, and atrophy of the nerve-fiber layer. The inner nuclear layer is thin. There is edema of the outer plexiform layer in the macular region. Retinal vascular changes are slight. There is a little serous exudate beneath the retina on the nasal

Fig. 12

Fig. 13

Fig. 14

Fig. 15

Fig. 16

Fig. 17

side. Occasional small hemorrhages are seen in the outer plexiform layer. A vascular membrane covers the optic disc and adjacent retina. The lamina cribrosa is depressed.

For comparison, there is presented the same clinical picture in eyes from two nondiabetic patients in the two following cases.

CASE 4. A. R., a women aged 61 years, had noted progressive visual loss in the left eye for five years. The eye was blind in two years. There was no inflammation nor pain until three weeks previous to examination, when the eye became very painful and inflamed. There were no symptoms referable to the right eye. General health was asymptomatic.

The eye examination revealed a vision of O.D. 6/6, and O.S. nil. The intraocular pressure (Schiotz) was 22 mm. in the right eye and 90 mm. Hg in the left eye. The external and fundus examinations of the right eye were normal. The left eye showed generalized injection of the globe. The cornea was edematous to such an extent that the fundus could not be seen. Transillumination was negative for evidence of intraocular tumor.

The slitlamp showed no evidence of anterior uveal disease. The pupil was slightly dilated and fixed. About the pupillary margin there was a ring of new-formed blood vessels on the surface of the iris, giving this sphincter portion of the iris a reddish hue. These new-formed vessels were very fine and individually could be seen only with magnification. Extending from this nearly diffuse ring of vessels to the base of the iris were several larger vessels on the iris surface. These latter vessels to some extent anastomosed with one another. The radiating vessels ended either behind the limbus or in small clumps of fine new-formed vessels on the peripheral iris surface.

Gonioscopic examination. The right eye showed normal angle markings and no new-formed vessels. The left eye showed complete obliteration of the filtration angle from anterior synechiae. New-formed blood vessels, both fine and coarse, were seen on the synechiae up to the point of adhesion with the corneal surface.

General examination. Blood pressure 180/110; physical findings otherwise normal.

Laboratory examination. Blood Kahn

Figs. 10-17 (Fralick).

Fig. 10. Case 3, right eye. Photomicrograph showing glaucomatous anterior-root synechia not entirely covering the corneo scleral trabeculum. Blood vessels not conspicuous in the scar.

Fig. 11. Case 3, right eye. Photomicrograph showing vascular membrane on anterior iris surface most marked in the sphincter region. Ectropion uveae is marked.

Fig. 12. Case 3, right eye. Photomicrograph showing vascular membrane on the surface of the optic disc and retina.

Fig. 13. Case 4, left eye. Photomicrograph showing malignant melanoma, Callender-spindle cell, subtype B, arising in the choroid.

Fig. 14. Case 4, left eye. Photomicrograph showing glaucomatous peripheral-root synechia without blood vessels' being a feature of the scar.

Fig. 15. Case 4, left eye. Photomicrograph showing vascularized inflammatory membrane on the anterior iris surface causing ectropion uveae. New-formed blood vessels prominent in sphincter and basal portions of anterior iris surface.

Fig. 16. Case 5, right eye. Photomicrograph showing peripheral glaucomatous anterior-root synechia without evidence of blood vessels as a prominent feature of the scar.

Fig. 17. Case 5, right eye. Photomicrograph showing new-formed blood vessels on the anterior iris surface at the sphincter region. There was no evidence of membrane formation on the iris surface in this case.

negative; urine showed no albumen nor sugar. Glucose tolerance test:

	mg. %	Urine
Fasting	76	negative
First hour	108	negative
Second hour	117	negative
Third hour	95	negative
Fourth hour	79	negative

Diagnoses. O.S., glaucoma (absolute); arterial hypertension. Rubeosis iridis.

Course. Intensive miotic therapy and 15 mg. retrobulbar mecholyl had no appreciable effect on lowering the intraocular pressure. The left eye was enucleated and sent to the Army Medical Museum.

Pathologic examination. O.S., Army Medical Museum accession number 75310. *Gross:* Firm eye coated with hemorrhage measuring 25 by 23 by 25 mm. The cornea is clouded and thickened. The eye is opened in the horizontal plane. The retina is detached, and behind it are firm translucent gelatinous exudates and a mushroom-shaped, deeply pigmented growth. The tumor mass measures 9 by 12 by 12 mm., and extends from a point midway between the optic disc and the equator to a point a few millimeters above the equator. The iris adheres to the anterior surface of the lens. *Microscopic:* Arising in the choroid just posterior to the equator is an irregularly pigmented mushroom-shaped tumor that has broken through Bruch's membrane and invaded the retina. Extrabulbar extension is not seen. Thin-walled blood spaces are abundant in the deeply pigmented portion of the tumor. The tumor cells are spindle shaped with oval nucleolated nuclei. A Wilder reticulum stain shows an argyrophil fiber content of more than 50 percent. Tumor type—Malignant melanoma, Callender-spindle cell, subtype B, choroid. Serous exudate occupies the anterior chamber. The iris is atrophic and shows anterior and posterior synechiae and ec-

tropion uveae. A few thin-walled blood vessels are seen in the membrane on the anterior surface of the iris especially in the sphincter region. (I believe that the vessels on the anterior iris surface which gave the ruby coloration to the iris about the pupil would have been more easily seen microscopically if adrenalin had not been instilled accidentally at the time of operation. Adrenalin compounds cause the rubeosis to disappear grossly.) The ciliary processes are hyalinized. There is lymphocytic infiltration of the choroid, particularly anterior to the tumor, and there is vascular engorgement posterior to it. Numerous colloid excrescences are present on Bruch's membrane. The retina is detached with serous exudate and pigment-laden phagocytes beneath it. It is adherent over the tumor, contains serous exudates, and is cystically degenerated and gliosed. Atrophic and degenerative changes are present throughout. The nerve head is invaginated, the optic disc is cupped, and the lamina cribrosa is depressed. There is perivascular lymphocytic infiltration of episcleral and orbital vessels.

CASE 5. W. F., a man aged 53 years, while feeding a printing press six weeks previously noted sudden loss of vision in the right eye. There was no inflammation nor pain until four weeks later, when the right eye became inflamed and painful. General health had always been good aside from a coronary occlusion two years before and a goitre operation seven years previously.

The eye examination revealed a vision O.D. of light perception, and O.S. 6/12. The intraocular pressure (Schiotz) was O.D. 90 mm., and O.S. 23 mm. Hg. The right eye showed generalized injection. The slitlamp examination revealed keratic precipitates on the posterior surface of the cornea. The cornea was edematous

to a slight degree. The pupil was dilated and fixed. Just outside the pupillary pigment border of the iris was a somewhat dense new formation of fine capillaries surrounding the pupil, giving the iris in the sphincter region a reddish hue. From this plexus of blood vessels extended straight or diagonally radiating vessels to smaller peripheral plexuses, some of which seemed to take part in the anterior-root synechiae. The basal anterior synechiae were very broad since they were seen through the cornea especially down and nasally. The optic disc showed cupping and atrophy. The retinal veins were full but only slightly tortuous. The retina appeared atrophic and presented innumerable hemorrhages throughout. The arteries showed moderate arteriosclerosis. The external and fundus examinations of the left eye were essentially negative.

Gonioscopic examination. The right eye presented complete anterior-root synechiae. There were foci of fine new-formed blood vessels on the anterior synechiae, the vessels in places reached the cornea and disappeared into the iris tissue. The left eye presented a normal filtration angle with no new formations of iris vessels.

General examination. Blood pressure 115/75; general physical examination normal.

Laboratory examination. Blood Kahn negative. Fasting blood sugar 91 mg. percent. Urine showed no sugar nor albumen.

Diagnoses. O.D., glaucoma (secondary). Occlusion central retinal vein. Retinitis hemorrhagica. Retinal atrophy. Rubeosis iridis.

Course. Intensive miotic therapy and retrobulbar injection of 15 mg. of mecholyl did not reduce the tension in the right eye. Adrenalin was instilled in the right eye, causing blanching of the rubeotic vessels of the iris, and the entire globe became white. The right eye was

enucleated and sent to the Army Medical Museum.

Pathologic examination. O.D., Army Medical Museum accession number 83612. *Gross:* The specimen consists of a firm eye measuring 23 by 25 by 24 mm. The cornea is clear; the pupil is dilated. The eye is opened in the horizontal plane. The disc is slightly cupped and the lens is opaque. *Microscopic:* There are peripheral anterior and marginal posterior synechiae. There are no conspicuous increases in the blood vessels at the junction of the iris and the posterior corneal surfaces. There is atrophy of the iris and vascularization of the pupillary zone. Only an occasional vessel is seen on the iris surface at the site of the anterior synechiae. No inflammatory membrane is noted on the anterior iris surface. The ciliary body is atrophic and the processes are somewhat hyalinized. There are multiple small colloid excrescences on Bruch's membrane. Multiple small retinal hemorrhages involve the nerve fiber, outer plexiform, and intervening layers. The retina has undergone atrophic changes, and in the macular region loss of ganglion cells, rods and cones, and of normal architecture is apparent. A little plastic exudate extends forward from the depressed optic disc into the vitreous chamber. Occlusion of the central vein is not seen in longitudinal nor in cross section. Vascular changes are not striking.

~ SUMMARY AND CONCLUSIONS

Four eyes in diabetics and two eyes in nondiabetics, all showing rubeosis iridis, were examined clinically and pathologically in an attempt to confirm or deny Fehrmann's contention that a differential diagnosis is possible between the two groups. Contrary to his findings in comparing the diabetic with the nondiabetic eyes, the writer could note no definite difference upon slitlamp examination in the

size or the disposition of the new-formed vessels on the anterior iris surface. Response to miotic therapy was absent in both groups. Both groups complained of intolerable pain to the degree that enucleation was required. A varying degree of iris atrophy was seen in the eyes examined, and yet the rubeotic vessels were still visible in all cases. This could be explained on the basis that the degree of iris atrophy was not sufficient in the diabetic individuals to cause the disappearance of these new-formed vessels. The glaucomatous scar in the filtration angle was essentially the same. The presence of a vascular adhesion between the iris and trabeculum or cornea was not a feature in the eyes of the diabetics studied. Dense tissue predominated in both groups. Unlike Fehrmann's findings, those of the writer showed the new-formed vessels to run in a layer of connective tissue attached to the anterior limiting layer in all eyes except in case 5, where no diabetes was found. There were new-vessel formations in and on the papilla and retina of two rubeotic eyes (cases 2 and 3) in diabetics and no such changes in the non-diabetics. This, however, is not a consistent finding in diabetics with rubeosis,

since two of the eyes herewith reported in diabetics did not show it.

Rubeosis iridis has thus been observed in patients showing rather varied pathologic conditions. One was a young severe diabetic with hypertension and extensive kidney damage; two cases were in more elderly diabetics, both having hypertension. It was seen in two nondiabetics, one having a hypertension and an intraocular malignant melanoma, and the other showing only what was diagnosed clinically as an old occlusion of the central retinal vein. In all of the cases presented herewith, the only common feature was the obvious circulatory disturbance to the degree that rubeosis iridis and hemorrhagic glaucoma developed. The writer, therefore, cannot support the contention that rubeosis iridis is a manifestation of an ocular syndrome seen in its true form only in diabetics. It is his belief that, given the right pathologic vascular supply to the eyeball, metabolic abnormalities will be established to promote a low-grade iritis with new-vessel formation and secondary peripheral-root synechiae, resulting eventually in hemorrhagic glaucoma.

OPHTHALMOSCOPY AND THE DIAGNOSIS OF HUMAN ILLNESS*

ARTHUR J. BEDELL, M.D.
Albany, New York

Edward Jackson (1856-1942), one of the greatest of American ophthalmologists, lived in Denver but belonged to the United States, for he travelled over the entire country, spreading the gospel of medical preparedness. Early in his career, he graced the Chair of Ophthalmology in the Philadelphia Polyclinic and School for Graduates in Medicine, and later as professor of ophthalmology brought renown and fame to the University of Colorado.

He had an unusual talent as an organizer, for, not only did he institute the Ophthalmic Section of the College of Physicians of Philadelphia, play a leading part in the founding of the American Board for Ophthalmic Examinations, which was the first and the model for all American certification boards, but in addition to these monumental achievements, he with Dr. Bane and Dr. Black started the Denver Ophthalmological Society, and later the Colorado Ophthalmological Society with its world-renowned summer course of intensive lectures and demonstrations. Unique in concept, this has

served as the stimulus to the founders of the many courses subsequently established elsewhere.

His qualities of leadership were demonstrated when he was chairman of the Section of Ophthalmology of the American Medical Association, president of the Academy of Ophthalmology and Otolaryngology, and president of the American Ophthalmological Society. In further testimony of his professional attainments, he was awarded the Lucien Howe Medal of the American Ophthalmological Society and the Leslie Dana Medal for conspicuous achievement in the field of preventable blindness.

Dr. Jackson was a prolific writer. More than 650 papers and addresses, as well as several textbooks, are evidence of his industry and the wide range of a brilliant mind. He made several original discoveries, and his work on skiascopy will always remain a classic.

When editor of the *American Journal of Ophthalmology*, the *Ophthalmic Year Book*, and *Ophthalmic Literature*, he reached a world audience.

Edward Jackson was a remarkable teacher. Endowed with a retentive memory and an alert, inquisitive mind, he recorded his observations based on reading and personal experiences in a most

* Colorado Ophthalmological Society Jackson Memorial Lecture. The lecture was illustrated with 100 slides; but because of the difficulty of reproducing photographs during the war, the illustrations are omitted.

impressive and convincing manner. Few ophthalmologists have ever ranked with Jackson the discussor.

The study of the life of Dr. Jackson, and his good works, will influence all who practice the healing art. I am, therefore, deeply sensible of the honor conferred upon me to inaugurate the Colorado Ophthalmological Society Edward Jackson Memorial Lectures, a memorial to a great scientist, a world-renowned ophthalmologist, an inspiring teacher, an erudite editor, a sympathetic humanitarian, and a wise counselor beloved by all who knew him.

Because of the many facts disclosed by ophthalmoscopy, this presentation is limited to a few selected groups. It is well known that there is a similarity between the fundus vessels and those of other parts of the body, and for that reason the inspection of the fundus supplies information not secured by any other method of examination.

Sudden closure of an artery leads to immediate partial or complete loss of function, which is either transitory or permanent, depending upon the nature of the local blood supply and the part of the body involved.

In the abrupt closure of the central retinal artery, the portion of the retina supplied by this vessel becomes pale, and, after turning white, the color gradually returns leaving two permanent signs—white, narrow, threadlike arteries and a white atrophic optic disc. When closure is caused by an embolus, there is no free retinal blood. The visual loss is irremediable and unaltered by medical or surgical intervention. I am convinced that when recovery is reported, the poor sight was the result of a spasm of the arteries and not the plugging of a vessel. To the internist, the patient with an embolus presents a problem, especially if there is no valvular heart disease or other evident

source of the obstruction. Most often the primary cause is not discovered, although endocarditic vegetations, fragments from a venous thrombus, or from an infected uterus, lung, or other organ may be the origin.

Immediate cessation of arterial blood shows as an interrupted blood stream with spaces between the cells and a slow propulsive pulsation of short excursion. Because the choroid shows through the thinnest part of the retina, the macular region remains colored, yellow, orange, or red. This so-called "cherry-red spot" is at first small, gradually enlarges, and often terminates in fine granules. The size of this area is, therefore, of considerable medico-legal value, for if the patient says he has just lost his vision and a large cherry spot is present, he is in error.

Frequently, patients are subjected to long and costly examinations to discover the cause of blindness in one eye, occasionally both, and not infrequently only a partial loss of one. Careful scrutiny of the retinal arteries will often confirm the diagnosis of sudden artery closure, and the impossibility of restoring vision. If the blindness is of spastic origin, the alterations in the caliber of the arteries are often visible but not always. The actual embolus has been seen and in branch block photographed.

Considerable time and energy have been spent on the interpretation of the sudden artery closure. Some competent clinicians believe the occlusion is the terminal stage of endarteritis, and we can readily agree when streak hemorrhages are found in the superficial retina. This differentiation seems to be borne out in clinical cases but has not been confirmed pathologically. When the physician thinks of these changes as occurring in the brain, for instance, he can understand the symptoms more clearly and forecast the end result with greater accuracy. Parentheti-

cally, it must be understood that the retinal vessels do not always reflect the state of the cerebral circulation.

In contrast to artery closure is vein occlusion, wherein the blood is retained within the eye, and the veins become distended with much or little bleeding in, on, or above the retina. The typical picture is well known; the disc outline is lost, the immense veins lie in the edematous blood-filled retina, and the central vein or branch is plugged.

The clinical course of closure is best studied in branch-vein block where, in the beginning, thin blood follows the retinal fibers in their arcuate distribution. The hemorrhage becomes denser, then whitish areas appear, gradually both blood and the white spots are absorbed as new vessels form the compensatory circulation. The closed vessels may become white lines or scarcely visible.

Total central-retinal-vein thrombus may terminate in one of three ways, complete resolution, organization of scar tissue, or glaucoma. The first two are similar to the general body terminations, and even the increased ocular tension, hemorrhagic glaucoma, may have its counterpart in the great, expanding swellings of cerebral-vessel thrombosis. The danger of a secondary destructive glaucoma is ever present. When the intraocular pressure is once elevated in thrombosis of the central retinal vein, it rarely, if ever, subsides, and usually causes an intolerable constant pain, which can be relieved only by enucleation. Organization is more common than complete resolution. Branch block rarely causes glaucoma, but it must be remembered that glaucoma may cause hemorrhage, and the differentiations between hemorrhagic glaucoma and thrombosis is an ophthalmologic problem. The vein closure may be from an embolus or the result of an endophlebitis.

Much has been written regarding

arterio- and arteriolar sclerosis. The ophthalmoscopic signs are not so clear cut as the discussions and the drawings suggest. It is essential to remember that arteriosclerosis and hypertension are not the same, for arteriosclerosis may be present with normal or even theoretically subnormal blood pressure. Incidentally, I heartily approve of any measures which the internists may promulgate to teach the public the truth about blood pressure, its interpretation, and real significance, for such knowledge will decrease the so-called hypertensive neuroses on one hand and on the other make those in real need of medical supervision seek a physician and follow his common-sense instructions.

In speaking about arteriosclerosis, it must be understood that vein compression, where the stiff artery presses the underlying vein or elevates the overlying one, is of significance only when the other signs of arteriosclerosis are present. Physiologically normal arteries may dent normal veins. Textbooks continue to stress the importance of twisting of the arteries as they cross the veins. This, I believe—and this opinion is based on photographic evidence—is much overrated and calls for a critical review. When the sclerosis is partial, white plaques may be found in the vessel wall; when more extensive, the wall may be white; and when extreme, the wall is widened to a broad, white band. The appearance depends upon the cause of the arteriosclerosis, as, for example, syphilitic vessels may be much more defined than those resulting from age and those from hyperpiesia may lie between the two and be either partial, disseminated, or general. Each case must be studied as an individual and the special alterations observed. Generalized arteriosclerosis gives a distinctive pattern of white arterial tree with a pale, or white, optic disc.

The sclerosis of choroidal vessels is a

favorable type for study, for the individual vessels in every layer can be isolated. Cases of sclerosis of both arteries and veins are found.

The close associations of prolonged hypertension and arteriosclerosis are recognized. There are, however, many degrees of hyperpiesia not separable into stages. They are too uncertain for that, nevertheless are demonstrable as progressive from mild to severe. A study of the patients operated upon for the relief of hypertension is enlightening. The reports of the fundus changes fail to show any correlation between the retinal pattern and the need for operation. At the present time, I do not advise sympathetic-system operations, for I am unconvinced of their value.

Clinicians must devote more time to the early diagnosis of hypertension. No region offers a better field for investigation than the fundus, where the earliest change may be an isolated, whitish-gray cloud in the superficial retina, the so-called cotton-wool exudate. This is always suggestive, and in this day of universal blood-pressure determination there is no excuse for overlooking its significance. Next in frequency are retinal hemorrhages of the superficial, striate type. Edema of the retina is an early and important change, and the constant need of appraising its increase or decrease is ever present, for when it is extreme all fundus details are indistinct, when localized to the nerve-head there may be a nasal side elevation or a complete papilledema so great as to suggest a serious, expanding brain lesion.

One should never forget that when a patient known to have had a comparatively negative fundus shows fresh changes, localized edema, or hemorrhages, these new signs should be interpreted as evidence of a beginning breakdown. When dark-brown or red granular hemorrhages develop in the deep retina, the

danger to life is acute and calls for the immediate consultation with the family. It has long been recognized that as time passes the retinal edema subsides; this must not be incorrectly interpreted as an evidence of improvement. The course of hypertension is one of interrupted or continuous progress. Many patients, especially women, have been seen for more than 20 years before any hemorrhage appeared and in many the systolic pressure was always 200 or higher.

More attention must be given to the signs of beginning decompensation. A single retinal hemorrhage may be the signal of approaching death and, if disregarded, danger lies ahead. The extensive exudates and the papilledema are more often recognized because of their grossness.

The ophthalmologist refers hypertensives to the internist with the knowledge that only by the coöperation of the patient can the best results be obtained. At times the situation is hopeless from the beginning, either because the disease is too far advanced or the patient so pessimistic that he will make no attempt to survive. The war is exacting an ever higher and higher toll of hypertensives because of the worries and anxieties coincident with the disruptions of life, and the excessive physical and mental exertion. Incidentally, a not-unusual early sign of hypertension is unilateral exophthalmos.

When considering the fundus changes resulting from nephritis due consideration must be paid to both arteriosclerosis and hypertension, for often it is difficult to separate the signs of one from those of the other. This is particularly true in cases of malignant hypertension with terminal kidney changes. When a patient whose fundus had shown no gross evidence of disease returns complaining of decreased sight, the fresh changes may be

so striking as to warrant a serious prognosis. Often such patients make no complaints about their eyes and yet retinal hemorrhages and exudates may be so numerous that one wonders why they have not appreciated their visual defects. The severe retinitis and neuroretinitis is familiar to ophthalmologists because it has been taught in all medical schools. At times a high N.P.N. is the only clinical evidence of the cause of delicate macular radiations. These disappear when correctly treated. The favorable cases are in marked contrast to those of massive exudates and hemorrhages, where the damage is not only irreparable but also irreversible and progressive. When first examined the retina may be edematous. As the edema subsides a macular star is formed; this is gradually absorbed but frequently the patient dies of uremia or cardio-vascular disease before it completely disappears. The understanding of the life cycle of the star is essential to accurate prognosis.

No fundus reflects the skin color more strikingly than does the red fundus in the fat, florid patient, nor the pale fundus in the nephritic with anemia. The importance of basing the prognosis on the underlying cause rather than on the disappearance of edema and exudate was photographically recorded in a young woman with nephritis. All the fundus landmarks were at first obscured by the extreme retinal edema, exudates, and waxy star. Immediately before death the edema disappeared and only a few isolated exudates suggested the former star.

The retinitis of pregnancy, although suggestively similar to other nephritic forms, is, however, often preceded by signs which are easily overlooked. The alert obstetrician knows that the first ophthalmic sign of danger is a spasm of one or more retinal arteries with transitory obscuration of vision. When the spasms

increase in frequency or duration, or both, a competent ophthalmologist must be consulted, for, if the patient is allowed to continue her pregnancy to term, a severe retinitis may develop, leaving a permanent pigmentary scarring or an optic atrophy; or a progressive hypertension may be initiated with papilledema and visual reduction, causing a severe curtailment in all physical efforts. The fundus picture of an acute pregnancy retinitis is the same as that found in any acute nephritis.

A fundus pattern somewhat like nephritis appears in traumatic retinal angiopathy, and is due to head injury, or chest or spine compression. The actual cause of the changes is unknown. Fat emboli have been suggested but not proved to be the activating agent. While speaking of the rare it is appropriate to say a word about angiomas of the retinae, Lindau's disease, because of the general as well as local manifestations. The characteristic fundus shows immense, tortuous veins and arteries with one or more angiomas into which the twisting artery can be traced and from which the vein can be followed. This is a familial disease, with brain cysts resulting from the small angioma. The picture, distinctive and once seen never forgotten, is of much interest to internists, neurologists, neurosurgeons and ophthalmologists.

Retinal angiomas may be very small and numerous, or large and single. Occasionally, a congenital anomaly shows dark aneurysmal angiomas like great bunches of purple grapes.

There are few conditions which cause more differences of opinion than does diabetes with retinal changes. The ophthalmologist sees extensive alterations and refers the patient to the internist with a note stating the diagnosis as retinitis in diabetes.

The internist reports that the sugar

level is normal and the diabetes is under control. The retinal signs change but rarely completely disappear. Perhaps the situation is hopeless but the number of patients, the functional loss, and the subsequent great mental upset call for a concentrated effort to solve the problem of their cure. To assist in the solution of the difficulty it is necessary to have a clear concept of what the retinal changes look like. The earliest signs are isolated, minute, round hemorrhages, or pinpoint exudates, or a combination of the two. In the cases of longer duration larger hemorrhages and larger exudates are present. The hemorrhages are frequently of the streak type, and the yellowish white exudates are widely dispersed in the posterior pole or in and about the macula. Frequently, these are thick masses, at other times isolated plaques similar to the lace crown of the so-called retinitis circinata. It must be thoroughly understood that there is no pathognomonic fundus pattern of diabetes, for all of the changes can be duplicated in arteriosclerosis, and even lipaemia retinalis may result from high cholesterol.

Sometimes, as for instance in resolving thrombosis, the small, hard, yellow exudates and scattered hemorrhages without marked retinal-vessel alterations are suggestive of diabetes and call for the exclusion of hyperglycemia as the first step in establishing the etiology. The retinitis in diabetes has a persistency which distresses all who care for it. Occasionally, large fundus hemorrhages become entirely absorbed, but more often they become organized as sheets of retinitis proliferans. The usual case of diabetes shows a rather constant change in the size and location of the exudates and hemorrhages. A critical analysis of 200 diabetic retinitis cases studied photographically, and several of them serially for a considerable time, seemed to prove that the

hemorrhages are not the forerunner of the exudates and, further, that in all probability the hard, yellowish-white exudates are not secondary to hemorrhages and, further, that the deep retinal hemorrhages do not become white specks.

The retinal exudates and hemorrhages seem to bear no relation to the efficacy of the diabetic treatment, for we have seen them in the so-called mild diabetes easily controlled by diet and others regulated with insulin. The retinitis may be present before any treatment is started, and in other cases, even when everything from the internist's standpoint is going nicely, fresh hemorrhages and exudates appear as the older ones lessen or disappear. The venous circulation is now under the spotlight of special study. The fundus changes in diabetics show a marked tendency to variation when no particular care or attention is given as well as when the patient is under the most approved scientific controls. Insulin does not increase the retinitis.

The imperative need of greater coöperation between internists and all interested in the eradication of diabetes is the result of several intercorrelated factors which can only be mentioned in this short clinical résumé. First, the introduction of insulin. The life expectancy of the juvenile diabetic has been considerably prolonged, and he is carried into adult life. Second, the relegation of arteriosclerosis as the cause of the fundus picture to a comparatively unimportant position. Third, the more competent and regular fundus examination of diabetics. Fourth, the seeming and doubtless very real increase in the retinal disease. Fifth, the almost complete lack of control once the retinal lesions have become fixed. This depressing fact is constantly borne in upon us, although occasionally the retina becomes clear and the exudates disappear.

Sixth, the longer the patient has diabetes the more he is predisposed to the refinitis. Therefore, juveniles are most liable to severe, invaliding visual disturbances. This emphasizes the well-known fact that many patients under seemingly perfect sugar control develop a progressive retinitis.

Finally, no treatment seems to retard or remove the evidence of retinitis. Some very competent observers believe without clinical support or experimental evidence that insulin induces it. Perhaps experiments with alloxan will supply the missing information and suggest the cure.

Tuberculosis is so familiar to you who live in this region of unusual good health that little need be said regarding it. Hemorrhage from a retinal artery may become absorbed and leave no trace. Tubercles may enlarge, new ones form and coalesce. In some patients hemorrhages are prominent and may disappear or form scars, or an expanding lesion or lesions, or a retinitis-proliferans sheet or veil. A solitary tubercle is most commonly in the macular area.

During the acute stage the vitreous is cloudy with a peculiar luminosity which makes penetration difficult, and photographs disappointing. Clinically, this seems to be very distinctive; in fact, a sign of clinical value. The tubercles of the acute miliary form are observed practically only in the terminal stages of the general disease. Choroidal tuberculosis has a tendency to recur as soft, gray, ill-defined masses which contract and finally heal. There are as many grades and types of tubercles in the eye as elsewhere in the body. It is especially interesting to follow cases similar to those so well described by Jackson and Finoff, where the tubercles lie in apposition to the vessels.

An evening could be devoted to the fundus changes caused by syphilis. It is conceded that there are two major sub-

divisions of involvement, the vascular and the neurologic, and that rarely do the two mix. This theory seems to hold in ophthalmology, where, if a patient has a choroiditis, he never develops a primary optic atrophy.

The vascular changes are small choroidal spots, often with a faintly pigmented border, well dispersed about the posterior pole. The graphic writers of other days spoke of this as a pepper and salt fundus. The grosser choroidal inflammations leave large or small, many or few pigmented scars, not absolutely diagnostic but suggestive of syphilis. Between these two are groups of medium-sized, round, heavily pigmented areas in the equatorial or peripheral regions.

Neurologic signs are optic neuritis with marked loss of vision and an elevated disc, and primary optic atrophy with sharply demarcated disc and progressive loss of visual field, ending in bilateral atrophy and blindness. Sometimes a child is infected, as, for instance, by a wet nurse. The optic atrophy is progressive. And, finally, a gumma may form in the optic nerve causing a pronounced swelling of the disc which eventually subsides, leaving a large, white scar.

The systematic blood states like leukemia, pernicious anemia, and polycythemia vera present, at times, extensive and suggestive hemorrhages and exudates which may be the first evidence of the approaching termination. Incidentally, it is time that the medical profession keeps blood-state tragedies out of the daily press, and that when a disease like acute lymphatic leukemia is under treatment the futility of transfusions be appreciated, so that valuable blood plasma may be saved for the Armed Forces instead of being wasted.

Because of the widespread interest and unwarranted optimism regarding night-blindness, attention is called to four

types. The classical, well-recognized, fairly common one is retinitis pigmentosa, an hereditary disease characterized early in life by impaired night vision. The loss is progressive until the patient becomes blind in the late decades of life. In this disease the fundus shows an equatorial zone of branching, pigmented cells, and a narrowing of the arteries and the veins leading to an optic atrophy. Nothing has ever checked the disease.

Closely allied to it is a childhood night-blindness without pigment, but white dots cover the fundus—retinitis punctata albescens. In advanced life, there is a superimposed pigmentation similar to that found in retinitis pigmentosa. There is also a form, nyctalopia, without pigment or white spots.

A number of patients with myopia are night-blind, and a careful inspection shows that the choroid is thin, suggesting the fourth group, choroideremia, which is a progressive dissolution of the choroid, eventually leaving only small islands of functioning choroid in the macular region and about the disc. Some syphilitics develop night-blindness and have a chorioiditis which may be ameliorated but not cured.

The time has arrived when the medical profession should arise to contest the unfounded claims of the publicity seekers who arouse unfounded hopes of cure and lead the disappointed in their rush to the charlatans.

No talk on fundus lesions would be complete without reference to papilledema, often called choked disc. It is advisable to disregard most of the textbooks and think of papilledema in the strict sense, an edema of the nervehead. In its earliest stages there is an increase in the translucency of the nerve fibers, obviously for anatomic reasons, first observed where the fibers are most numerous, in the nasal portion of the disc. As the

edema increases, more and more of the fibers swell, and as a result they surround the central excavation. This cup is retained even when secondary exudate and hemorrhages obscure the disc margin. Often it is recognized only by careful stereoscopic examination and photographs, and for that reason has not been given its proper position in the diagnosis of papilledema.

Time, the duration of the pressure, plays an important role in the individual variations for, other things being equal, the longer the process the greater the disc changes. An inspection of the nervehead in prolonged intracranial pressure will readily confirm this statement. Other elements enter into the production of choked disc, and in this brief account mere mention of them must suffice. In the course of some acute mastoiditis cases the edema of the disc may be of considerable degree and lead the uninitiated into a panic of reoperation. Usually, the condition is transitory and quickly subsides. The disc is of the smooth, rounded type, with few or no hemorrhages in contrast to the papilledema of the sinus thrombosis, where hemorrhages are, both early and prominent. Similar in gross appearance is the papilledema from orbital abscess, orbital cellulitis, ethmoiditis, sphenoiditis, or sinus thrombosis. The swelling is often unequal, there being more on the side of the greater compression, if and when both sides are involved.

The wet brain of syphilis causes disc swelling of variable degrees, and the papilledema of hyperpiesia may be so extreme as to call for the most discriminating analysis of all the physical signs and symptoms, including X-rays and air injections before the final diagnosis of high blood pressure is made. This is at times a very difficult task, for brain tumor may be present in a patient with hypertension, and unless operated upon the termination

is fatal. The usual hypertensive choked disc is a smooth, rounded swelling, varying in color from yellow to water-soaked gray. This is in contrast to the choke of thrombosis of the central vein, where immense veins and extensive retinal hemorrhages are dominant.

Brain tumors are the major cause of choked disc, and the physician of today is ever alert and always studies the ocular fundus in any patient with headache. Too much stress cannot be laid on this essential procedure to prevent some patient from being operated upon for nonexistent sinusitis while some others, labeled neuropsychopathic, will receive the benefit of modern neuro-surgery. Several years ago, Parker reported on the difference in degree of disc swelling and said that it was greater in the eye with the lower intraocular pressure. This may have some bearing on the cases of frontal-lobe tumor, where one disc is swollen and the other atrophic, the Foster Kennedy syndrome. An arachnoiditis causes papilledema, and, when of traumatic origin, a crown of blood surrounds the elevated disc. The hemorrhage may even flood the retina. The error of confusing optic neuritis with papilledema persists, and yet few observers will frankly state that the classical signs and symptoms need revision. The disc may be greatly swollen in what proves to be a neuritis, and the reverse, little swelling, found in a papilledema. All reference to the diagnostic importance of the degree of disc swelling should be based on the practical understanding of the process. Textbooks say that up to 2 diopters it is optic neuritis; when greater, papilledema. A fairly safe clinical rule is to think of neuritis when reduced vision is the dominant symptom and the visual fields and

the disc changes confirm the impression. In choked disc the average patient complains of general symptoms such as headache, nausea, and vertigo rather than loss of vision, and only the ophthalmoscopic examination discloses the swollen disc. Much can be done and will be in the near future to lessen the confusion that leads to delay in diagnosis and postponement of corrective treatment. Enough has been said to elicit interest in segregating the pressures from the inflammations, which include disseminated sclerosis and acute myelitis.

In closing, a word to those especially concerned with treatment of patients in advanced life. Geriatrics is not a specialty. All who practice medicine appreciate that there is a wide discrepancy between chronologic age and tissue maturity. The subject is fascinating, but we can refer to only one of the age tragedies, senile macular degeneration. The patient complains of difficulty in reading, may drift about and buy several pairs of glasses before the macular lesion is discovered. This is at first a small central, retinal or choroidal hemorrhage, then an edema of the retina followed by cellular infiltration and an expanding ring of superficial and deep blood. It may be years before the scars causing the central scotoma and impaired central vision become stationary. The patient is unable to read, becomes very apprehensive, and unless told that he will never go blind as a result of the disease, may become despondent. Therefore, my closing message is to understand and explain senile macular degeneration as well as the other innumerable fundus changes, a few of which have been presented for your review.

344 State Street.

A DISCUSSION OF OCULAR MALINGERING IN THE ARMED SERVICES

ARTHUR C. UNSWORTH, LT. COL. (M.C.), A.U.S.

A discussion on malingering in the Armed Services is not satisfactory until a definition for the term is agreed upon. The one given by Balser¹ is adequate: "Malingering is a conscious design or effort on the part of a serviceman to escape service in the Armed Forces by assuming a physical or somatic illness or by magnifying consciously any organic illness which in itself is not a basis for a discharge from military service." The first recorded definition, as published in Groves Dictionary in 1785 is "A military term for one who under pretense of sickness evades his duty." For the purpose of this discussion, the term will be confined to military life and not include civilian deceptions such as the claiming of illness or injury for the purpose of obtaining a compensation in civil life. The writer believes that the term should be reserved to indicate feigning of the serious sort, principally reserved for feigning to attempt to avoid all military duty, to avoid combatant or other hazardous service, or to obtain a discharge from the military service; and he agrees with Waud² that the terms "gold-bricking" or "soldiering" and other less severe terms should be used for minor conscious feints to avoid duty or work which are very common in military life; the intention to avoid these duties in itself is not punishable. The half-hearted attempt of inductees in the preliminary examinations when not persisted in, should hardly be called malingering, as when a draftee, upon being asked to read as far down on the chart as he can see, says that he has poor vision in one eye and reads only to 20/100, but if urged will soon read the 20/20 line. Malingering, then, as a term should be reserved for the persistent,

conscious, willful design and effort on the part of the man to tell and demonstrate his simulated physical or mental defect rather than weakly to mention that he has this condition. The malingerer is fixed in carrying out his purpose to a result.

Malingering must be clearly differentiated from other simulative manifestations. As Brussel and Hitch³ point out, it is conscious and excludes the phenomena of the psychoneurotic, particularly of the hysterical and anxiety neurotics whose symptomatology is the unconscious ego requirement finding externalization. Carpenter⁴ states that it is difficult for many medical officers to accept the fact that malingering and psychoneuroses are distinct clinical entities; the treatment for one is useless for the other. Psychoneurosis is an actual illness. The malingerer⁵ lies, the other tells what he believes to be the truth, although it may be true that neither wants to return to duty. Though Grinker and Spiegel⁶ say that the greatest problem associated with malingering is the ready conclusion by many medical officers that mild neurotic symptoms and true conversion phenomena can be simulated. It is true that some psychoneurotics exaggerate their symptoms more or less unconsciously to gain their ends, which makes it difficult to differentiate where neurosis ends and malingering starts. The crucial differential point between malingering and a psychoneurosis is that malingering is conscious and a psychoneurosis is unconscious. Some malingerers, as Rosenberg⁷ asserts, have a constitutional psychopathic personality, but, on the other hand, some are cool and calculating and seem to have no evidence of psychopathic

personality other than a lack of conscience. Many are below average intelligence.

In my experience of 18 months at the Connecticut induction center, the incidence of ocular malingering was fairly high before Pearl Harbor, averaging about 7 percent in selectees examined, but it dropped off very markedly when war was declared, probably to 2 or 3 percent. In a large basic training center where 500 to 1,400 newly arrived trainees were medically processed a day we found the incidence of ocular malingering to be less than 0.5 percent. Agatston⁷ says that in routine army-induction examinations it was between 0.5 and 3 percent. Waud² asserts that it is most common among selectees during the first year of service, new recruits, and among those who have been assigned to the guardhouse, or among those who have undergone disciplinary action. Grinker and Spiegel⁶ saw only one or two cases in Tunisia. Brussel and Hitch,³ at the Fort Dix Station Hospital, found that of all cases referred for neuropsychiatric consultations 7 percent were diagnosed as malingerers. Statistics of malingering, like all other things medical, may vary greatly when taken by two men examining the same group. One physician may include only the true, persistent, conscious simulator, another the half-hearted attempt to deceive, and even the exaggeration of illnesses and defects that most psychoneurotics are prone to exhibit. Again the experience of another observer may be only with picked combat troops.

The cause of malingering is inherent in all of us. Gainer⁸ says that "evidence of malingering is exhibited very early in life, making it seem almost an innate characteristic of man." Bowers⁹ points out that many soldiers have been inducted into the service against their will or to

their financial, educational, or social detriment. These men consciously or unconsciously grasp at any possible physical ailment that may improve their present situation. This was particularly true of the selectees inducted before the war, when the reason for compulsory military service had not yet crystallized and any method of avoiding service was condoned by families, friends, and even in some instances by public officials. Once war had been declared, malingering to avoid military service became an unpatriotic and cowardly offense and one not committed by good citizens. There are only three aims in true military malingering, as Agatston⁷ points out; namely, to avoid all military service, to obtain limited or perhaps noncombatant status; or to obtain a discharge from the Army with or without compensation. However, by men in exhausted states, after long, unpleasant, and dangerous military duty, it is sometimes used to obtain temporary rest, recreation, and good food. In this instance it is questionable whether the malingering is part of a psychoneurosis or not. I do not agree with Brussel and Hitch,³ who say that malingering is unquestionably a form of inborn constitutional psychopathic inferiority, although Grinker and Spiegel⁶ think that the basis of malingering is usually a highly neurotic background. Usually, as Miller¹⁰ says, the difference between a malingerer and the man who goes sick with feigned or exaggerated symptoms for small things, is that the latter is satisfied to be given a chance to escape from a false position without undue loss of self-respect. This latter class is the group which passes on into hysteria frequently, if not recognized and reprimanded. In viewing malingering, the cause and the time of occurrence should be fully considered. For instance, combat troops or flying personnel may refuse to go back

into action, others may feign illness or injury to avoid returning, and still others may have a true conversion hysteria, depending upon the moral and mental stability of the individual. The first instance is the brazen but honest individual, the second is the underhanded and dishonest man, but neither has neurotic symptoms and usually little feeling of self-condemnation, because of his own rationalization. As Grinker and Spiegel⁵ point out, these soldiers have simply not adapted their ideals to the current military environment and have little conscience about their conduct. They behave as if they have done their share and the rest is the responsibility of someone else. This is often the expressed attitude of many previously brave and successful fliers. I saw a flying officer who had returned from many missions over Germany, and who on being given the examination for flying claimed just poor enough vision in both eyes to avoid further flying combat duty. On being detected, he simply stated that he felt that he had enough combat duty and was lucky to return alive. He felt that someone else should take his place. The more brazen type is illustrated by the case of a bombardier who, when he was sent to the hospital for a simple operative correction of an extraocular muscle imbalance, refused to have the operation performed because if his muscle balance was corrected, he would return to flying duty. This he did not wish, because he said that he had sufficient combat and chose to remain within the continental limits of the United States. He signed a statement to that effect. Apparently, refusal to return to duty or "partial" malingering is more commonly found in this war than conversion hysteria such as was found in World War I, which Strecker¹¹ believes may have been due to

the relatively few ground troops engaged. It is probably also due to the mobility of the present warfare.

Detection of malingering, in general, depends upon the alertness and experience of the examiner. After working for some time, particularly in induction examinations, one feels that he can sense the malingerer as soon as he comes into the room. Most malingerers enter the examination room with an unusual attitude; it may be bellicose, aggressive, or it may be with a great deal of timidity. The gait and manner in which the patient handles himself usually arouse suspicion. Simulation¹² is always in keeping with the extent of the knowledge possessed by the individual regarding the particular disease from which he pretends to suffer. It is always impossible for the healthy person to feign the entire picture of the disease he has selected, thus the examiner can usually detect omissions, discrepancies, and contradictions. Cozen¹³ and Grinker and Spiegel⁵ suggest the use of morphine or hypnotic drugs to uncover simulation and to secure confession.

In detecting ocular malingering, each case should be treated as an individual problem, because the means of detection that are successful with one man may not work with another. In the preliminary or early military examinations it has been the writer's experience that many men who premeditate malingering are discouraged from it by a somewhat bellicose and aggressive manner on the part of the examiner; and if malingering is attempted, intimidation by threats, ridicule, or sarcasm is often discouraging, at least to the naïve and unpracticed simulator. If the malingering is persisted in, the examinee is best stood to one side; and I believe that the man should stand up while awaiting a more opportune time for lengthier examination. Standing in

one spot for some time under apprehension as to the results of the delayed examination is very exhausting and discouraging to many men. This crude approach does not work and should not be used on the more hardened, intelligent, and experienced malingerer. For men of the latter type who are usually encountered later in military service and who wish to avoid being sent to combat duty, the concealed sympathetic approach is more successful, for it puts the malingerer off his guard and secures better cooperation. A complete history should first be taken, including that of his family, for often psychic disturbances in a parent give a clue to the background of the man's actions. The time of occurrence and believed reason of onset of the claimed disability should be determined. Most psychoneurotics date the disability from some very definite emotional event, whereas the malingerer frequently is vague about the time of onset and its etiology. The protracted examination and prying questions irk the malingerer, but the hysteric eagerly answers all questions. The actual examinations should be made rapidly, and a careful record kept. During the actual examination it is well to have witnesses present with a view to the possibility of later courtmartial. Once sufficient evidence of malingering is secured, ridicule, sarcasm, and an attitude of disbelief may be adopted. This may be injected insidiously but clearly, to let the falsifier know that his simulation has been detected. He may be sent away to return for another examination, when he will sometimes admit his deceit. The element of surprise is sometimes useful; for example, suddenly telling the man he is a liar and asking him the reason. This often unnerves the malingerer, and a confession may be obtained. If possible it is well to have a signed confession; few

malingers, however, will sign an incriminating paper except by intimidation, which would not look well in court-martial.

In cases of doubt, reports of previous examinations by oculists or optometrists with record of the patient's vision can usually be obtained, for if the patient has deficient vision even in one eye he usually is cognizant of the fact, has sought medical aid at some time, and is frequently wearing glasses. However, too much reliance should not be placed on ocular examinations just prior to induction in the Army, because in some instances the inductee has gone to an oculist and malingered on the examination in the doctor's office to establish evidence of poor vision. There have even been cases in which the physician falsified his report of vision. Many states require a visual examination before an automobile driver's license is issued, and usually their record of vision can be readily obtained from the Motor Vehicle Department. If insurance has been taken out, the insurance company or its local representative may have a record of vision. Many of the larger industrial concerns give preemployment examinations and will have a record of the man's vision. Knowledge of the previous occupation of the examinee will often throw light on the approximate vision necessary to perform a certain task. Information regarding the patient's vision may also be obtained through the Red Cross, the patient's neighbors, or relatives.

There are six forms of malingering,² and these may be divided into positive, in which the man attempts to prove his falsification, or negative, in which he falsely denies history or physical signs of existent disease or injury:

(a) By simulation, the symptoms of an injury or disease which does not exist

are feigned.

(b) By falsification, the signs of the disease are misrepresented.

(c) By false attribution, the cause of the disease is falsified or there is the assignment of an untrue cause to an actually existent disease or injury.

(d) By exaggeration, the signs and/or symptoms of an existent disease or injury are intentionally increased.

(e) The disease or injury is intentionally inflicted by the man himself or by his request and with his knowledge.

(f) Dissimulation is the pretense that a real disease or injury is not present or is less serious than it really is. Or the man may deny the existence of prior injury or disease before coming into the service in order to obtain compensation or discharge. All forms of malingering fall into the aforementioned categories or a combination of them.

SPECIFIC TESTS FOR DETECTION

A. VISUAL. It is important, in making most of the visual tests, that the patient should not close either eye during the examination, and a very careful and constant watch must be maintained by the examiner to see that this order is carried out. The more practical tests only are herein described.

1. *Claim of partial loss of vision in both eyes.* This is the most difficult falsification to prove and is the one most frequently used. It is also the most frequent simulation of the conversion hysteric.

a. The retinoscope and ophthalmoscopic examination will readily establish the approximate refraction of both eyes and the probable visual acuity without glasses. For examination of large groups, ophthalmoscopic examination usually provides sufficient information regarding the refraction. The table prepared by Agatston⁷ gives approximate

vision for refractive errors without correction.

b. The correction worn in the man's glasses usually gives the approximate refractive error, but occasionally there have been found men who have just obtained glasses with large amounts of correction for the purpose of establishing a record of poor vision without and even with glasses. An emmetropic person, for instance, may wear heavy minus lenses; and, indeed, it is not infrequent to find that the optometric examiner may have prescribed a good deal more minus power than the patient requires.

c. To determine the acuity of vision without glasses, especially in the myopic, a minus lens with a balancing plus lens may delude the patient into believing that he has his correction before his eyes when actually he has the equivalent of plano. This will give the record of vision without glasses.

d. In the army age group there should be little difference between visual acuity for distance and near. The correlation between Jaeger and Snellen type is valuable, or between Snellen type and test objects.

e. The manner of reading the test type may arouse suspicion. If a person can read all the letters on a certain line correctly he can always read a few of the letters on the next smaller line. The malingerer will frequently read without hesitation down the chart to the end of a certain line, then stop and refuse to see any letters on the next line. On the other hand, he may read every letter on the chart with equal hesitancy and effort as if it were just as difficult for him to recognize the 20/200 line as the 20/50. Again, he may deliberately miscall certain letters. The letter "L" hardly looks like any other, an "F" may be called a "P," or "C" an "O," but if "C" is called "T" when other letters on the same line

are read correctly it arouses suspicion.

f. When partial loss of vision of both eyes is claimed, probably the most valuable test is changing the size of the visual angle by testing the individual at varying distances as 20 feet, 30 feet, 10 feet, 5 feet; 10/20, for instance, is the approximate equivalent of 20/40.¹⁵ If careful checks are made with recordings of vision many malingerers will give themselves away because they do not know which line they should see at a given distance. One occasionally sees a man who has been coached for this examination beforehand. A mirror test with special chart in which the letters are reversed is valuable, because frequently the malingerer does not realize that a chart seen in a mirror is the equivalent of twice the distance to the mirror.

g. If much difference in the visual acuity is claimed, the same tests as those for partial loss of vision in one eye only may be used.

h. Negative malingering to enter the armed services or to maintain a certain status must be kept in mind. Squeezing the lids together to make a stenopaeic slit improves vision in cases of refractive error. I have encountered two cases in visual testing in which contact lenses were being worn by commercial airline pilots seeking Air Corps commissions. To my embarrassment, it was not until finger tension of the eyes was taken that this subterfuge was discovered.

2. *Partial loss of vision in one eye only.* The history of the length of time there had been poor vision in the one eye, history of injury or eye operations are most important. Merely because one eye deviates or has deviated does not necessarily mean that the eye is amblyopic; many squinters have 20/20 vision in both eyes, particularly the true alternators. Exaggeration of slight amblyopia is common.

a. Gradle's test with three polaroid discs.¹⁵ One polaroid disc is placed in the trial frame before each eye with the polarizing axis horizontal. The individual is then asked to read the smallest line of letters on the test chart with both eyes open. While reading, the third polaroid disc which has been inserted before the good eye, is rotated so that the polarizing axis becomes vertical. This rotation of the third disc prevents any passage of light to that eye, so that if the reading of the test chart is continued during this time it is evident that the poor eye is the one being used. If the patient stops reading when the good eye is blotted out by polarization, one may start again one or two lines higher and repeat the procedure to determine which line the man can actually read with his poor eye.

b. Polaroid discs with a projection apparatus.¹⁴ A polaroid disc is set in each side of the trial frame with the axes at right angles to each other. A third disc is placed in a projection apparatus and is rotated so that the reading of the test letters of either is blocked out at will. This has the advantage that the trial frame on the patient is not touched at all during the examination.

c. The Snellen test with colored letters on glass illuminated from behind.¹⁵ A test card of special red and green letters on glass may be used with a red glass before one eye and a green glass before the other. The red letters will be invisible to the eye which has the green glass and vice versa. This also may be done by having letters of different color on paper. Most projection apparatus which project red and green letters can be used as well, or the ordinary duochrome check.

d. Test with trial lenses. The refractive correction is placed in the trial frame before each eye. A high plus lens is then placed in front of each eye. The plus lenses are gradually reduced in strength

but much more rapidly for the allegedly poor eye, so that in a few changes only the refractive correction is before this eye. With each change of lenses the patient is asked to read. When the plus is reduced to the refractive correction of the poor eye the best visual acuity with correction of this eye is obtained because the vision of the good eye is still blurred.

e. The bar-reading test of Cuignet.¹⁵ An object such as ruler or tongue depressor is held vertically between the patient's eyes. The reading material, such as the Jaeger card, is held at about 35 mm. away, so that the whole of any one line cannot be seen with either eye; part of each line being covered by the ruler. The subject is then asked to read the smallest print that he is able to. If he reads an entire line he must be able to see it with both eyes, otherwise the portion of the line read with the poor eye would be blurred.

f. The Bishop-Harmon diaphragm apparatus.¹⁵ A test card with graduated letters is held by the apparatus, which consists of a holder at reading distance with a diaphragm held between the holder and the patient's eyes, so that in looking through the diaphragm the patient sees the left-hand letters on the test card with the right eye, and the right-hand letters with the left eye, which confuses him. The visual acuity of the poor eye is thus determined. The same thing can be done with the phoropter provided by the Army, or with the stereoscope, by removing the partition.

g. The test of reading Snellen chart at varying distances and reading in the mirror can be used as described.

h. Duane¹⁶ describes the test of asking the patient to read aloud rapidly and suddenly placing a 4-degree prism up or down before the poor eye. If the eye is very amblyopic and there is no fusion, there will be no effect, otherwise the con-

fusion resulting from the diplopia will make reading poor or impossible.

i. The Harlan test. A +12D. spherical lens is placed before the good eye and a +6D. lens before the other eye. The examinee is given a Jaeger card to read which is held close enough so he can read the test card with the good eye. The card is then gradually withdrawn and if he continues to read when the print is out of focus for the good eye he must be using the amblyopic eye. The degree of visual acuity in the amblyopic eye can thus be determined.

j. Lasky¹⁷ describes Jackson's cylinder test. Two cylinders are placed at right angles to one another before the normal eye, giving the equivalent of a sphere; the correcting lens is also placed before each eye. The patient is directed to read rapidly and one of the cylinders is slowly rotated, blurring the vision of the good eye. A +2D. sph. and the same minus cylinder with their axes parallel may be used before the good eye.¹⁸ As the axis of one lens is rotated, the vision of the good eye becomes blurred.

k. The stereoscope with reading-test cards is useful, such as Keystone cards or others in which some of the letters or numbers are seen with one eye and some with the other. The Keystone test has the advantage of having the test letters of varying size, so that the acuity of the amblyopic eye can be determined.

l. Bakker, according to Lasky,¹⁷ describes a modification of the colored-letter test. The Snellen chart is illuminated with red, green, or yellow rays from a lamp; the patient is fitted with his corrective lenses. The examiner puts a green glass over the patient's good eye and turns on the green light. The patient finds that he can read with his good eye only. The red glass is then put over the good eye, the red light put on and the patient again reads it with his good eye.

Another red glass is put in front of the good eye and a sodium lamp is turned on, or the green lamp might be turned on and, since the rays are absorbed by the glass, he then reads unknowingly with his bad eye.

m. If the good eye is occluded first and vision of the poor eye is tested, many patients who are simulating will read so many lines from the top, or so many lines from the bottom. If one cuts away one or two lines of the top of the chart so that the top line is 20/70 and adds other lines at the bottom such as 20/10 lines, the patient will often be induced to read the equivalent number of lines of smaller visual angle than he has accustomed himself to and so will admit better vision to that degree.

3. *Total loss of vision of both eyes.* The history is very important. The onset of the blindness and the manner in which it occurred is asked. Fundus examination may reveal no pathologic change, which immediately excites suspicion.

a. Pupillary reactions are important. Any accommodation-convergence reaction immediately uncovers simulation, but this is difficult to induce in the patient. Reaction to light is possible even though both eyes are blind if the visual fibers are intact to the geniculate body. Usually the pupils are semidilated in blind eyes and do not respond to light.

b. The optokinetic-nystagmus test attributed to Bach¹⁸ causes a horizontal jerky nystagmus when the subject fixates objects that are moving, such as those seen from a moving train. The optokineticoscope is a vertical drum, about 10 inches in diameter, which has alternate black-and-white vertical stripes, each one inch wide. This drum is mounted vertically on a central rod and revolved slowly. The patient is induced to look toward the drum and, if nystagmus results, the patient must have visual fixation in at least

one eye. It is important to revolve the drum slowly and to have the instrument at the usual reading distance from the patient.

c. Watching the patient cross a room and his manner of approaching objects, such as a stool or chair placed in his path, is valuable. If he is simulating blindness he will usually avoid the object or rush at it and fall over it with unusual force.

d. Most people who simulate blindness wear dark glasses probably in order that by so doing it is possible to prevent observation of the movement of the eyes behind the glasses. The true amaurotic patient does not wear them as a rule.

e. The induction of instinctive reactions on the part of the person can be used. For instance, if a menacing action is made quickly and unexpectedly in front of the patient, or a very bright light is flashed in his eyes, the normal tendency is to flinch and blink and thus vision is proved.

f. The Schmidt Rimpler test.¹⁴ The patient is asked to look at his hands. The actually blind individual will rotate his eyes toward his hands, while the malingerer will look elsewhere purposely.

g. Electro-encephalography¹⁹ has been used. The alpha rays are present in electro-encephalography when the eyes are shut, in blindness, or when there is a uniform light or dark field of vision. They stop when there is enough vision to distinguish large objects. These alpha rays come from the occipital cortex.

4. *Total loss of vision of one eye.* All of the tests used for amblyopia of one eye can be used with these additions:

a. Pupillary reactions are useful. If the eye is blind the consensual pupillary reaction should be present in the blind eye but absent in the good eye, and the direct reactions will usually be absent in the blind eye but present in the good eye.

b. The Jackson test¹⁵ can be used. A

6-degree prism, base down, is placed before the good eye; the muscle light at the other end of the room is turned on. If two lights are seen, binocular vision is proved.

c. A 10-degree prism, base out, is placed before the blind eye. If there is fixation in this eye and fusion, diplopia will be momentarily induced and the eye will rotate inward to correct it and fuse the two images.

d. A 10-degree prism, base down, is placed before the good eye so that its edge lies horizontally across the center of the pupil while the other eye is occluded. This produces monocular diplopia when the man looks at a distant light. If the prism is then moved upward in front of the good eye and the blind eye is simultaneously uncovered, and diplopia is admitted, there is sight in the blind eye.

e. Strong cylinders¹⁷ of the same strength are placed one before each eye but at right angles to one another. The patient is requested to look at a test light which is flashed on at the other end of the room. If a luminous cross is seen, vision is present in both eyes. Maddox rods can also be used for this.

f. Van Sisley, according to Lasky,¹⁷ makes use of the physiologic blind spots. Three white spots are placed on the tangent screen so that the center spot can be fixated with both eyes and the left-hand spot will fall on the blind spot of the left eye and the right-hand spot will fall on the blind spot of the right eye. If a diaphragm, such as a vertical ruler, is placed between the two eyes just in front of the face, the left blind spot cannot be seen with the right eye and vice versa, so that with both eyes open only the center spot is seen. If the diaphragm is then removed, three spots are seen with both eyes open or if one eye is occluded entirely two spots are seen, the center and the left hand spot with the right eye; and the center and right hand spot with the left

eye. The patient can be tricked into giving the wrong answers.

g. The patient may be placed in a dark room and told to close both eyes. The occluder is held in front of one eye or the other, so that the patient cannot tell which eye is covered; and then a narrow beam of light is flashed on the uncovered eye. If light is seen through the lid of the blind eye, vision in that eye is proved.

h. The perimeter may be used in taking a field with both eyes open. If the test object is seen in the area in which the nose occludes or blocks the vision of the good eye, vision is proved in the poor eye, which is the reverse of Cuignet's confrontation test, in which the examiner passes an object across the field of vision of both eyes and the dishonest subject denies having vision in the nasal field of the sound eye.

B. DEFECTS IN VISUAL FIELDS. The most common and best-known defect in the visual field in malingering or hysteria is concentric contraction, usually demonstrated by the spiral field in which the visible area on the test apparatus seems to grow smaller as the examination proceeds, so that finally the field is reduced to 5 or 10 degrees from the center, or even less. A false tubular field may also be simulated; and this can be detected by testing the fields of vision at different distances from the tangent screen, in which case the malingerer usually maintains exactly the same-sized field at different distances—for instance, 10 cm. from the center—even though the visual angle has changed. The color fields may be reversed. Most simulated defects in fields are easily detected by the examiner.

C. NIGHT BLINDNESS is a not infrequent complaint of men assigned to sentry or other unpleasant duty at night. This symptom is frequently complained of in early basic training, at which time many cases of retinitis pigmentosa or

myopia with retinal degeneration and night blindness are discovered. Kreieleis²⁰ says that by repeated examinations with the Comberg adaptometer, the malingerer cannot remember his adaptation. The Hecht apparatus can be used even better. The American Optical Company instrument is not so well adapted because it depends on length of time, which is rather easily remembered. The value of Harman's test,²¹ using varying-sized colored discs, is questionable. McDonald²² states that the complaint of poor night vision frequently manifested by poor landings at night is one of the earliest manifestations of an anxiety state in fliers.

D. PHOTOPHOBIA is a frequent complaint in the tropics or semitropics. If it does not disappear with the wearing of dark glasses (in the absence of a visible evidence of pathologic change), it can be assumed to be a manifestation of malingering or psychoneurosis. Many psychoneurotics complain of photophobia, and the wearing of tinted lenses in any individual without adequate reason is an indication of the possibility of a psychoneurotic personality.

E. DEFECTIVE COLOR VISION is rarely simulated and could only be used to relieve a person from flying status. This can be readily discovered by using the American Optical or Ishihara plates or one of the colored-light or -yarn tests. Negative malingering is much more common but can always be detected by these same tests if done properly.

F. EXTRAOCULAR MUSCLE IMBALANCE. The most common complaint of the malingerer on this score is diplopia. There can be no binocular diplopia unless there is a muscle imbalance, either a phoria or a tropia, and unless some degree of fusion is present. Except in the case of paralytic strabismus, any complaint of diplopia should be regarded with suspicion. If the diplopia is of long

standing before induction into the Army, it cannot be very annoying. It is important for the examiner to recognize these facts before testing and treating any extraocular-muscle imbalance. We recently saw a case of unilateral congenital fibrosis of the external rectus muscle. The man was not aware of the condition and had no symptoms until it was accidentally discovered in an examination at a nearby station. The examiner evidently thought that since there was a divergent strabismus upon looking in one direction and a convergent strabismus upon looking in another, diplopia must be present, and ordered an occluder for the involved eye. The man was finally sent to the hospital and the actual condition was discovered. The occluder was removed, the condition was explained to the patient, and he was returned to duty. Now he complained of diplopia even though he had no fusion. This man had a psychoneurotic personality originally, but he has since developed a neurotic fixation because of the poor judgment of the medical officer who ordered the occluder.

Nystagmus can occasionally be simulated. Voluntary nystagmus is pendular and may be unilateral or bilateral. The movements are usually rapid and may be in any direction. They are increased on fixation, convergence, and by increasing the palpebral fissure. It disappears by distracting attention or by blurring the vision, such as by placing a +20D. sphere in front of both eyes. I have seen two such cases in the service. It is produced at will and is not associated with any pathologic entity.

G. PTOSIS is occasionally simulated, but it is a difficult simulation to carry out consistently. It is usually adopted by persons of low intelligence and is easily recognized by having someone hold the individual's head firmly and asking the patient to follow a test object as it moves

in all directions of gaze. In true ptosis, the eyes usually elevate although the lids do not, but in false ptosis it is impossible to elevate the eyes without elevating the lids at the same time.

H. LAGOPHTHALMOS AND EXOPHTHALMOS, unilateral or bilateral, can occasionally be produced artificially in talented individuals. But these conditions cannot be maintained voluntarily for long and are soon recognized if nonpathologic.

I. ASTHENOPIA is a frequent complaint of psychoneurotic individuals, particularly if they are doing close work. On the other hand, adequate cause in refractive error, muscular imbalance, or incorrect and inadequate lighting may be discovered. If there is no ocular pathologic change and no other adequate cause can be determined, psychoneurosis or malingering should be suspected. In conjunction with asthenopia headache is a frequent symptom and must be investigated thoroughly before it is waived aside as a simulation. Most simulators of headache are soon detected in actions such as prolonged reading, loud talking, roughhousing, or other boisterous activities which are not well tolerated by one having real headache. A placebo drug may also be given.

J. CILIARY SPASM is occasionally met with in anxiety neurosis or hysteria. I recently saw a man who had a bilateral severe ciliary spasm of 10 or more diopters which was intermittent and seemed to be produced at will without any discoverable cause. On psychiatric consultation there was no other evidence of a psychoneurosis. I never was sure whether the condition was voluntary or not. After the condition had been explained to the soldier he was sent back to duty and has not been heard from since.

K. CONJUNCTIVITIS artificially induced by placing foreign bodies, such as glass and sand or other articles, in the

conjunctival sac^{23,24} has been frequently described, but apparently rarely seen during this war. Few men are willing to damage their eyes intentionally, because of the high value placed on the organ of sight.

L. VOLUNTARY BLEPHAROSPASM is occasionally seen. It is apt to continue in spite of local anesthetic drops; when a true blepharospasm disappears. Unilateral blepharospasm is not infrequent when diplopia is complained of.

M. INTRAOCULAR DISEASES are almost impossible to simulate. However, exaggeration of the symptoms, such as defective vision, is not uncommon in these cases. The usual tests for defective vision are used. False attribution is occasionally seen when the individual tries to obtain an Army discharge or compensation for nonservice-connected ocular pathology.

Negative malingering is a frequent occurrence, an attempt being made by the examinee to cover up ocular pathology in order to enter the services or to maintain combatant or flying status.

Although the incidence of malingering is not high in this war, it is important that any attempt at it is effectively dealt with in order to discourage it in other examinees. I agree with Farrell and Kaufman¹² that whenever it appears to the examining physician that an individual is endeavoring to escape service by malingering, if otherwise mentally and physically fit, he will be accepted. I also agree with Bowers,⁹ who says that the patient's bluff should be called and if he refuses to be a good soldier, punishment should be immediate and of a severity in keeping with the nature of the case. I cannot agree with Brussel and Hitch⁸ that the malingerer should be prevented from gaining entrance into the Armed Forces and that should prevention fail he should be detected and eradicated by discharge, and

should be returned to the community whence he originated. This policy if followed through would place a high premium on falsification to the detriment of the honest individual. It is imperative that line officers as well as medical officers be on the lookout for malingerers. If a case is detected and action is taken word soon gets around that malingering does not pay, if the punishment for this crime is sufficiently severe. Even "goldbricking" and other minor feigning of illnesses should be discouraged. But the major form of malingering to avoid military service, to obtain discharge from the service, or to avoid combat should be treated like any other crime, such as stealing. This is not treated as a psychoneurotic disorder, and neither should malingering. Any malingering that succeeds lowers the morale of the whole organization. It would seem that now that we are at war a stricter policy should be adopted, and the individual should be punished with due regard to the gravity of his offense. The medical officer should remember that his job is detection only, that corrective action is the duty of the man's commanding officer. A psychiatric consultation should be obtained on all malingerers, to differentiate between neurosis and malingering,

and if courtmartial is ordered it is well that a psychiatrist be present at the trial. Prophylaxis for malingering is even more important and is accomplished by the same means that Strecker¹¹ advises as prophylaxis for neuropsychiatric disabilities. There is a significant relationship between malingering, war neurosis, and morale in the troops. High morale depends on several local factors in the soldier's environment: 1. Healthy training conditions. 2. Sufficient and good-quality food. 3. Sufficient exercise. 4. Supervised sports, and other diversions. 5. Medical care that inspires confidence. 6. Good relationship between the men and officers. 7. Rigid discipline and drilling, which inspires a sense of group security. 8. Talks to groups of soldiers on the psychologic aspect of fear and its understanding. 9. Most important is a clear perspective and appreciation of the ideology for which the war is being fought and the value to the individual, his family, the nation, and the world of maintaining this ideology.

Acknowledgement is made for the helpful suggestions and criticism of Lt. Col. Edward H. Williams in reviewing this paper.

PATRON SAINTS OF THE EYES: AN OUTLINE*

FERDINAND L. P. KOCH, M.D.†

New York

Healing through saints in early and medieval Christian centuries transcended that by physicians, who were secondary and enjoyed only scant encouragement when saintly personages could be invoked to cure. Man, animals, and the heavens were set by custom in fixed categories: Man was above the beasts but below the angels; he was foreordained to worship God, but all else had been created to serve man. Dissenters forfeited their rights and privileges and were punished publicly. The Christian martyrs, many of whom became saints, were among these because their professed beliefs dif-

fered from those of others in the community.

Lacking the solace of scientific reason, refuge was sought in superficial explanations of terrors of Nature. These developed as narratives that increasingly were employed to diminish the unreasoning fear engendered by abnormal activity of the elements. Thus, naturalistic legends ensued while supernatural legends evolved as stories of the saints.

Miracles. A great variety have been reported in some detail but Brewer questions whether all of those vouched for by the Fathers during the first three centuries of the Christian era should be accepted since by far the great majority of all recorded miracles occurred during that single period of time. Sight has been reported to have been restored to persons of all ages and to both sexes and to those who were born blind as well as to those who had become sightless. Miraculous cures most often apparently were

achieved by the laying on of hands, the making of the sign of the cross, by prayers or by other words, by an attitude of gaze, by bathing the eyes in water used by the healing one, or by a combination of two or more of these methods. The recipients of the return of vision are anonymous in the main or are identifiable only briefly. Very rarely supernatural powers were invoked to effect blindness in an offender.

Popular faith in miracles, particularly in times of illness, evolved from the intimacy of suffering attendant on the close relationship of the sick and the saints. However, as Pettigrew observed, in part, "... all miraculous cures are of the same description, the disorders are similar, and the effects described are precisely the same. It is faith which works the miracle. . . ." But Le Bec, staunch in his belief that there must be recognized the existence of "a mysterious force emanating from the Holy Eucharist," stated: "Miracles are not made to order." Miracles, in the Christian legends which are as venerable as Christianity itself, instanced the intervention of God in such fashion that intangibles assumed reality: The impious suffered righteous punishments and the devout were rewarded and their prayers were heard. The early Western Church only secondarily and with reluctance supported this faith in miracles and in saints, but its blessing permitted the glorification of the miraculous in ecclesiastical art and indirectly was largely responsible for the biographic portrayal of the saints as we know them at present.

Saints. The term (from the latin, *sanc-ti*, and the Greek, *hagioi*) refers to members of a Christian community but is applied particularly to those who lived in Jerusalem (Dan vii. 18 sqq., et cetera). The deeds and lives of some individuals indicated exceptional possession of piety and spiritual grace, and this character

was attributed in natural course especially to those who had suffered martyrdom. This first was expressed in the letter of the Smyrna congregation. Communities kept registers of those Christians worthy of public veneration, and this was permissible only by order or authority of the bishop. These names were recited at the Eucharist. Hutton states: "From these diptychs (lists) came the kalendars, and from the kalendars in later days the martyrologies." And it is from the latter that the legends developed.

Christian martyrolatry replaced pagan worship of the dead, but modified pagan *parentalia* became birthday feasts and festivals of the martyrs. Thus, paradoxically, veneration of the saints permitted expression in part, at least, of the basic heathenism which the Church had supplanted. Prayers for saints at eucharistic oblations were transformed into intercessory appeals. Every altar had its relics, and chapels of saints received the sick as once did the temples of Aesculapius. Amulets became a part of the dress, and no important undertaking, personal or communal, was initiated without invoking the aid of appropriate saints. Success usually necessitated a formal expression of gratitude, and recovery from illness after saintly intercession caused the presentation of medical votive offerings to churches, chapels, or altars.

Hagiography. The "depositio martyrum" in the calendar of the Roman chronographer (354 A.D.) is the oldest known calendar, or almanac, dealing with the lives of the saints; however, only the barest biographical facts are recorded and, since these did not satiate the faithful, there developed the hagiographic legend as a literary device to cater to numerous local preferences and mores. These legends entertained as they instructed, edifyingly in religion and morals but, prior to the thirteenth century, they had

been collected only in liturgical manuscripts and differed little from those written from the fourth to the sixth centuries. These Christian legends served originally to epitomize asceticism and martyrdom and to create an apochryphal history of the apostles from the stories of their lives in the Gospel; known facts of genuine martyrologic instances embellished incredible tales for the credulous, and central figures were so interpreted as to leave no doubt of the virtues and joys implicit in the practice of Christian principles. Not infrequently, however, the only historically demonstrable facts in a particular legend are the name of the saint, the fact of canonization, and the date of the festival in question.

The foremost hagiographer, Jacobo da Voragine, the Archbishop of Genoa, portrayed the lives of the saints in his "Legenda aurea." His stories were not new but were arranged in order as in the several calendaria. He constantly moralized under the text of august example, and he was a diligent, uncritical recorder of tradition. As an educator he made available to the many the lore which, in his day, was largely the property of the few with access to monastic lectionaries. His stories were comprehensible to all because of their direct, even coarse, pliant style. Reference so often was made to current moods and beliefs that the work appealed widely to a sorely tried but indefatigably optimistic age. It became the most popular work of the Middle Ages and exerted considerable influence on the arts. It had none of the appearance of the work of an individual; its tone was more that of the accumulated folklore of all Christendom. It provided the average Christian with an escape from the narrow geographic boundaries and the restricted social barriers of his daily existence. And equality of mankind gained a partisan whenever it was learned that the

wealthy and the poor knelt as equal supplicants.

Intercessory specialization. Appeals to formerly unknown saints for assistance against certain maladies resulted increasingly in specialization. This refinement is an extension of a constant tendency since earliest antiquity to request special protection for particular bodily parts. Saints as patrons of specific diseases generally were chosen as such because of some appropriate miracle thought to have been performed during the life of that saint, or in some specific detail of martyrdom, or in a peculiarly tonal association of the name with that of the part or of the morbid condition. This association of names, so current among the more humble of the populace, was not to be found in the almost inaccessible, obscurely written, liturgical manuscripts, and it was not until the thirteenth century that Jacobus first integrated them into his "Golden legend." Ecclesiastical art visually portrayed the saints thus popularized and aids in interpretation not only of the supernatural legend with reference to ophthalmology but also, of the associated artistic masterpieces.

SAINT LUCY

Those suffering primarily with external diseases of the eyes invoke the aid of Saint Lucy, a virgin and martyr of Syracuse in Italy (Sicily). Historically, it is known that she was born into the nobility in about 283 A.D., of wealthy Christian parents. Her Italian father's early death left her dependent on her devoted Greek mother, Eutychia (or Eutitia). Lucy, as did many other early martyrs, desired to consecrate her chastity to God and worked constantly to devote her anticipated material wealth to the use of the indigent; however, her mother, who held control of the property, did not agree with this noble resolve until after her

chronic, intermittent vaginal bleeding had ceased while praying at the shrine of Saint Agatha in Catania where she had been taken by Lucy (Lucia). Brewer has given the story of this miracle in some detail: Lucy prayed to Saint Agatha to intercede for her mother and, while still in prayer, the saint appeared with heavenly angels and said, "Sister Lucy, why ask of me what you can yourself give unto your mother? Make your petition to God, for be assured if He loves me, He no less loves you also. If He will hearken to my prayers, so will He unto thine. If I am honoured as a saint here in Catanea, you shall be honoured as a saint in Syracuse."

Lucy found her mother restored to health and persuaded her to permit distribution of most of their wealth among the poor; however, the pagan youth to whom she had been unwillingly betrothed objected to this openhandedness and reported her unfavorably as a Christian to Paschasius, the governor of Sicily. She was found guilty and condemned to prostitution but she stood so immovable in the strength of God that even four oxen could not drag her from the spot where she stood (fig. 1). Further tortures and indignities then were forced upon her, but her faith in God still was so unswerving that her death finally was accomplished only when her throat was punctured by a sword. Baring-Gould pointed out: "... with Saints . . . when everything else seems ineffectual to hurt them, cold steel breaks the charm." This is depicted in the Predella Panel: Martyrdom of St. Lucy (fig. 2). The symbolism of light as well as her attributes is portrayed by others (figs. 3 and 4).

Saint Lucy's most careful historians mention her blindness as one of her most grievous torments, but there is no documentation concerning the actual loss of her eyes: Mention of the latter does

not occur either in her "Acta" or in any of the earliest legends, but early artists expressed her name, Lucia (or *lux*), by placing an emblem of an eye, or eyes, near her in their works. Jameson not infrequently encountered such instances "of the convergence of the image or metaphor into a fact," and it is most probable that from such sources there developed the additional supporting incident or incidents in the history of her life.

Jameson also reports that many references exist with regard to the loss of Saint Lucy's eyes. This apocryphal narrative tendency apparently developed several centuries after her historic martyrdom. It is related, for example, that a young man of her acquaintance in Syracuse, although he expressed his deep love for her in every ardent fashion, found it unrequited. Her eyes had so captivated him that he was unable to think of anything else. Lucy felt not only that her vow of chastity was in danger but she also feared for the safety of her suitor and, bearing in mind the dictum of Christ, she plucked out her offending eyes (the method is not given) and sent them to the young man on a salver. He then, worthily enough and in atonement for the deep injury he had initiated, was converted to Christ and lived thereafter in virtuous chastity. However, it was not ordained that the pure and blessed Lucy should remain sightless; as proof of her courageous piety, her eyes suddenly were restored more pristinely beautiful than before as she knelt one day in prayer.

Saint Lucy, according to the many works dealing with the lives of the saints, is among the most illustrious of the virgin-martyrs and was so honored at Rome in the sixth century. Her feast day is celebrated annually by Latins and Greeks and by many warm-country Catholic peoples on the 13th of December, which

also is the festival of Saint Odile. This coincidence has given rise to some confusion. Saint Lucy, in a painting by Albertinelli which hung in the Munich gallery, is recorded in the German catalog as Saint Otilia; however, the latter was an abbess and, in all devotional pic-

tures, properly is so represented. The 13th of December was a date known throughout the Middle Ages, especially in Western and Central Europe and in the Mediterranean countries, as the night of Saint Lucy, when demons and phantoms roamed the earth spreading illness.

She popularly was believed to spend that night annually dispersing evil spirits and warding off whatever malignancies they were perpetrating. Her feast, even today, is observed nationally in Sweden, a predominantly Lutheran country, when on that date a girl of each family, dressed all in white and wearing a lighted crown of candles, appears at dawn and offers coffee and "Lusia cakes" in honor of the saint who symbolizes the return of the light of day and the bringing of cheer (fig. 5).

Saint Lucy is the principal patron saint of Syracuse as well as of Alife, and she is a minor patroness of Palermo and of Mantua, Italy. She is invoked not only primarily against diseases of the external eyes but against ocular diseases in general as well as the loss of sight. She is believed also to protect against sore throat, epidemic diseases, dysentery, and any type of hemorrhage. The laboring poor, ploughmen, and tillers of the soil venerate her as their patroness. Her festival was celebrated as one of the second rank in England until the Reformation, and no work except tillage was permitted on that day. Swainson mentions in his "Weather folk-lore" with reference to the 13th of December, the day of martyrdom of Saint Lucy: "Lucy light, the shortest day and the longest night." Jacobo da Voragine, introducing his chapter on Santa Lucia, says: "Lucia means light. Now the aspect of light is beautiful for by its very nature it contains all classes. Hence we must understand that St. Lucia possessed the ornament of immaculate virginity; that in her was an outpouring of heavenly love without any impure passions. Her prayers went directly to God, and she passed the whole day in charitable works, without pause and without vexation. Or Lucia also means *lucis via*, a path of light." Blake writes: "There is a manuscript, written

in 1220, preserved in the dome of the Milan Cathedral, and cited by Gottofredo of Bussero, stating that Lucy took her name from 'light.' Cardinal Frederick Borromeo, in the sixteenth century, in his book, "On sacred paintings," mentioned a connection between Saint Lucy and the pagan divinity Lucini, who was also recommended for ocular troubles."

Artists and sculptors, great poets and writers, and even an explorer, have done homage to Saint Lucy and have added to her renown. Santa Lucia, an island in the Lesser Antilles, was discovered on the 13th of December and named by Christopher Columbus in her honor because, it is related, he had been cured of ocular trouble by her intercession; however, de Ybarra does not confirm this, although it is possible that chronic uveitis coexisted with the rheumatism (and not gout) from which Columbus suffered throughout his adult life.

The devout poet, Dante, professed such great devotion for Saint Lucy that he stated in the "Convivio" that he would name one city for Mary and the other for Lucy if he had a total of only two to name. He wept so copiously over Beatrice that Saint Lucy cured him when his eyes were affected. The light, exhilarative joy aroused by thoughts of Saint Lucy is expressed in the Neapolitan Boat Song, "Santa Lucia."

Many artists have portrayed Saint Lucy in many attitudes, media, and in a variety of styles. Details of her martyrdom; her emblems, the cord and eyes; the lamp symbolic of illuminating grace; the two eyes placed on a dish, a salver or on a missal held in her hand or situated nearby; the poniard, dagger, or sword; and the blessed palm of martyrdom are depicted individually or together in the various paintings, sculptures, glasswork, polyptychs, altar pieces, predellas, and bas-reliefs. The earliest works, as well as

those of later centuries, portray her holding a palm as the symbol of her martyred death for the sake of Christianity while the two eyes figure in some fashion more prominently in the later works. She consistently has been endowed in art with the character of celestial light and wisdom. Among those who have thus represented her are Tiepolo (in the Church of the Holy Apostles, Venice), Luca della Robbia (in bas-relief, over the door of the Church of Saint Lucy, Florence), Domenico Veneziano (in an altar piece in the same church), Barroccio, F. Angelico, Luca della Robbia (Church of Santa Maria a Ripa, Empoli, Italy), Carlo Dolce, Giovanni de Spagna, Lello da Velletri, Antonio Riccio, Parmegianino, Bernardino Luini, Antonelle Gaginia, le Perugin, Lodovico Brea, Arcangelo Aquilini, Jacopo Avanzo, Pesellino, Angelico da Fiesole, Benedetto del Ghirlandajo, Niccola Grassi, Pietro Alemanno, Crivelli, Garofalo, Bartolo di Fredi Battilore, Lorenzo Costa, Gabriele Capellini, Domenico Ghirlandajo, and Lorenzo di Niccolo Gerrini.

SAINT ODILE

The recorded biographies of Saint Odile (Otilia, Odilia, Otilia, Othilia, Obdulia) are considered by Waite to illustrate the growth of a legend the romance elements of which have been woven about certain other basic facts that appear to him to have been fairly well authenticated historically.

There is in French Alsace a Mount Hohenburg which is said to have been a retreat of Alsatian Celts who protected it by a wall. It became a Roman camp for a time but, in the latter half of the seventh century, Adalric, Duke of Alsace, was in possession of this site on which a castle already had been erected. Adalric (Adalrich, Adalricus, Etic, Ettico, Aticus Etik—*Vatican spelling*), or the Alemannic

duke, Eticho I, was an imperious nobleman of his time who owed allegiance to his King, Childeric II, a reputed descendant of Archinould, Duke of Normandy, and a near kinsman of Dagobert the Great. Adalric married Bereshinde (Bereswinda, Berswinde), a relative of Saint Leodégar (Léger). The "Life" of Saint Odile (the "Vita" written in the tenth century), embellished with many legends, makes the claim that she was a niece of this saint. It is stated in the Catholic Encyclopedia that there exists a shorter text contained in a manuscript of the early eleventh century but that "internal evidences point to an original eighth century biography" although these are not specified.

A daughter who was born blind in about 660 A.D. was the first issue of the union of Adalric and Bereshinde. The enraged father lost no time in condemning her to immediate death; however, her mother secretly placed the infant girl in the care of an old female servant. Vision was reputed to have been bestowed upon her during adolescence, and, after parental reconciliation, she became a nun and the abbess of a convent which was actually the Castle of Hohenburg. She lived there for nearly a century and died in sanctity as a monastic saint.

The other recorded details of the narrative of Saint Odile are less well authenticated. She is said to have been transferred by her mother for educational purposes from the care of the old servant to the Convent of Baume-les-Dames, the Mother Superior of which was an aunt of Bereshinde. Despite her blindness she was instructed in learned matters and became a patron of intelligence and of piety although she never had been baptized. It was at this period of her life, when she was somewhere between the ages of 6 and 12 years, that Saint Erhard (Erard, Everard, Erhardt, Eberhard, Herard), a

bishop in the commissariate of Ratisbon, presumably fell into an ecstasy during which he received a call to proceed to Baume in the Rhineland to christen, by divine inspiration, a blind girl who was to be called Odile and who would receive sight with the sacrament. The promised miracle immediately followed baptism and, as she opened her eyes, according to Jacobo da Voragine, Saint Erhard said to her: "May you look at me thus in Eternity, my daughter;" or, according to Waite: "So, my child, may you look at me in the Kingdom of Heaven."

Adalric, shortly after the return of Odile's sight, was informed not only of the existence of a daughter whom he thought dead but, also, of the occurrence of the miracle. Accounts vary with reference to whether Saint Erhard was the purveyor of this news or if her brother, Hugh, had approached his father with the information. It is agreed, however, that Adalric, this unnatural parent, became very angry and not only refused Hugh's request that Odile be permitted to return home but he forbade any mention of her name. Hugh sent for Odile in spite of the parental edict and he was standing with his father on a neighboring small hill when she arrived in a carriage accompanied by a small crowd of local peasants. When Adalric learned the identity of the traveler and the manner of coming to his castle he fell upon Hugh and effected his immediate death. Adalric then turned, however, in immediate remorse to his daughter and, after gazing at her for the first time, became as affectionate as he had been cruel.

Odile came to prefer to live in quarters provided by her father at Obernai. It is inferred that she wished to continue the type of activity for which she had been trained. She lived and worked for several years at Obernai with a few recruited companions who joined her in devotions

and charitable works among the poor. Her father, upon her attainment to womanhood, arbitrarily arranged for her marriage to a German duke. Upon learning of this plan she fled, closely pursued, in beggar's clothes across the Rhine and, as she was about to be captured by her father at the Schlossberg near Breiburg in Breisgau, was forced to hide under a rock beneath a cliff face. This opened miraculously to her prayer and gave her refuge. Her father again was profoundly impressed by the evidence of another new miracle when the rock opened to liberate her, with a new healing spring issuing from the fissure. This spring is consecrated and still flows at Odilienberg (Hohenburg) where there is a long vista over the Rhine Valley, Alsace, and Baden. It still is visited by many pilgrims seeking not only the curing waters for their ocular troubles but, also, the intercession of Saint Odile. There also is to be found there a small chapel dedicated to her honor; however, it is not claimed that this is the same chapel that she is said to have had built on the spot in commemoration of the event when the rock gave her sanctuary.

When a reconciliation with her father was effected, consultations ensued, and she opened her heart to him, after which he permitted her to return to the family estates in complete freedom. She then expressed her desire to establish a convent of a community of nuns for the purpose of the literal practicing of the principles of the Gospel. He was prevailed upon to present to her from his various possessions his Castle of Hohenburg, situated behind Obernai. She altered the premises to suit her purposes and converted them into a convent to which Charlemagne granted immunity. This was confirmed on the 9th of March, 837, by Louis the Pious, who also endowed the Foundation. She became the abbess of 100 nuns and

added a great church, in the chapel of which she was buried.

Saint Odile established a rule of life, probably on principles of her own, in her convent, but there exists considerable difference of opinion, according to Waite, with regard to whether this was of her own devising, that of Saint Benedict, or that of Saint Augustine. Pilgrims travelled to the convent in increasing numbers, but the steepness of the mountain was a discouragement and an inconvenience; subsequently, she founded an auxiliary convent at a lower level on the eastern slope of the Mount (fig. 6). This she named Niedermünster and attached an inn, or hospice, to it.

Both her mother and father died in this convent during her long and useful life. She is said to have succeeded in rescuing her father from purgatory by receiving supernatural assurance that her prayers and penances for him had been answered. In about 720, on her deathbed at the age of 103 years, on the 13th of December, which, like that of Saint Lucy, is celebrated as her feast day, she was presented, it is related, with a chalice containing both elements of the Eucharist. She received it into her hands from a radiant angel in the sight of her nuns. It is implied by some authors of the lives of the saints that it was Saint John the Baptist who appeared to her and who also indicated at that time the site and dimensions for a chapel which he wished her to build in her honor. It is believed by others that this is more likely to have occurred at some time prior to that of her death, and this is indicated by the portrayal of Saint Odile and Saint John in an old work of Meckenem (fig. 7). The chalice remained with her after the communion and was placed in Hohenburg in 1546, in which year the abbey was destroyed by fire on the Vigil of the Assumption. The abbey was destroyed and rebuilt several

times subsequent to its first destruction. Some believed that the relics of this saint were preserved in spite of these events but the fate of the heaven-sent chalice is unknown.

The cult of Saint Odile grew, and she became the patron saint of Alsace. Hohenburg (Odilenberg), which later was said by the faithful to contain the relics of its first abbess, became a renowned mecca for holy pilgrimages. Saint Odile, who is invoked for ocular affections, usually is represented in ecclesiastical art with two eyes reposing on the pages of a missal, or prayer book, and her vestments are those of an abbess, by which she is readily distinguished from Saint Lucy, to whom is granted the same emblem together with a martyr's palm and who is also commemorated on the same day, the 13th of December (fig. 8). Baring-Gould has observed ambiguously that there may exist some difficulty between recognition and invocation of these two saints by reason of the narrative crediting Odile's miraculous acquisition of eyesight by baptism.

SAINT CLAIR

Saint Clair (Claire, Clarus, Clarius), whose feast is celebrated on the 4th of November, was a priest and martyr of the ninth century. He is invoked, chiefly in northern France, by those afflicted with inflamed eyes. Ophthalmia, according to Gordon, was known as Saint Clair's disease, but the term probably was employed generically rather than specifically. Saint Clair after having been elevated to the priesthood in England went to Normandy and lived as a hermit at Le Vexin (Vernon), in the Diocese of Rouen, adjacent to the Diocese of Beauvais.

There is much repetition of the name Clarus and of its derivatives in the several calendars, almanacs, and dictionaries. This may have been the result of carelessness by earlier compilers, or it may

have been due to the tonal association of names as well as to geographic inaccuracy. The French Benedictine, Usuard (Usuardus), according to the Benedictine Monks, of St. Augustine's Abbey, Ramsgate, placed the name of Saint Clair in the Roman Martyrology as of the ninth century. The English Menology, however, gives rather wide limits concerning the time during which he lived covering the period of 666 to 894. There is further confusion concerning actual dates because the Roman Martyrology in its chronological listing mentions a Saint Clarus whose feast is celebrated on the 8th of November and whose epitaph Saint Paulinus is said to have written. This Saint Clarus, who died a few days before his Master in 399, was a priest at Tours, an important community on the main highway to Paris from Nantes and Orleans.

Another Saint Clarus who is said, according to the Benedictine monks of St. Augustine's Abbey, to have been known to have lived and gained local fame in Normandy in the Middle Ages may very well be the Saint Clarus registered in the Roman Martyrology. Baring-Gould does not diminish the investigative difficulties by adding that Saint Clair occasionally is represented as a bishop, thus being mistaken for his namesake, Saint Clarus, a bishop of Mantes, which is a community situated between Paris and Vernon on the River Seine. Nor is it an aid to learn that there is still another Saint Clarus. The latter was an aged pagan priest at Roche-Guyon (upstream from Vernon on the River Seine), and he was converted to Christ by Saint Nicasius of Rouen after the former had been cured of blindness by the latter. The nature of the blindness is not specified, but Clarus later was ordained a priest and suffered a martyr's death (for reasons not recorded) with Saint Pientia of Roche-Guyon. Martyrdom occurred in approxi-

mately 311. The feast day of this Saint Clarus is celebrated on the 11th of October. And, lastly, there was a martyred Saint Clarus who was a bishop of Apt in southeastern France. He is the local patron against sore eyes and also the patron saint of tailors. His relics are in the parish church of Apt, where formerly his festival was celebrated on the 2d of January, but he now is honored also at Saint Cannot's Church in Marseille on the 9th of February.

In the interests of clarification some geographic mention should be made of northern France in the valley of the Seine. This is the region where the principal Saint Clair flourished, and this is fairly evident since the various compilers make similar mention of the several communities associated biographically with saints possessing this name. It seems most probable that there existed only one important Saint Clair who was invoked by those afflicted with inflamed or sore eyes, and it is his story that will receive particular attention here. It also may be observed that the name, "Clair," derives from the old French, meaning "clear," which, when usurped as a name for contemporary holy persons gained the further significance of spirituality of grace, gaze, and of mind. It is speculative whether Saint Clair chose his name in France or if he acquired it earlier in England. It was not an uncommon name in the France of his time, but it was not brought to England until the Norman baron, Walter de Bienfaite, of Clair (the treaty town of Clair-sur-Epte), in France, gave the name early in the tenth century to the English town now known as Clare.

Saint Clair was purported to have lived for many years a life of great seclusion and severity, in emulation of the Fathers of the Egyptian Deserts, after he had gone to Normandy from England to live

in the then province of Neustria. He is reputed to have led a hermit's existence near Coutances, south of Cherbourg, after which he became a monk at Maudun. He attempted, as a hermit, to teach true religion by word and precept to those among whom he lived, and he continued to follow these principles throughout his life.

He settled after long wanderings in Le Vexin, either in or near the Diocese of Rouen or that of Beauvais. The story of his martyrdom relates that he lived somewhere in the neighborhood of a lady of rank whose amorous advances he so frequently was compelled to repulse that it became necessary for him to take refuge in the forests in order to avoid revengeful death at the hands of two servants the spurned woman had sent to murder him. It is inferred that his eyes were of such beauty that he unwittingly caused the burgeoning of unrequited love in the unfortunate woman. His repeated flights ultimately, however, did not prevent his eventual beheading (fig. 9; see also fig. 4).

Saint Clair is among the few English saints represented in the famous wall paintings in the chapel in the Venerable in Rome. His martyrdom is appropriately symbolized, since he is represented as carrying his head with one hand while bashfully covering his eyes with the other as, presumably, was his attitude when the lady cast her admiring glances on him. Although Saint Clair is invoked throughout northern Catholic France by those with diseased eyes, there exists no available record of specific instances of ocular cures effected by his intervention.

It is necessary in connection with Saint Claire to digress briefly with regard to Saint Clare (Claire, Clara, Chiara, Cera) of Assissi, who was a virgin saint and foundress of the Poor Clares. She was born on the 16th of July, 1194, at Assis-

si, in central Italy, and took the vows of the ascetic life at the age of 18 years. She governed a community of nuns for 40 years, the last 27 of which she lived in illness. Pope Innocent III granted sanction for the privilege of extreme poverty and of living solely on the alms of the beneficent. It is from this custom that her order has ever since borne the title of the "Poor Clares." Her festival is held on the 12th of August, but she is celebrated only locally in Italy and in isolated communities elsewhere as a patroness against sore eyes. No specific instances of miraculous ocular healing are accredited to her; however, she is frequently depicted carrying or holding a lighted lamp (fig. 10).

SAINT AUGUSTINE

Saint Augustine (Augustin, Aurelius), Confessor and the Bishop of Hippo Regius, was born on the 13th of November, 354, at Tagaste in Numidia. He is included by name in the Canon of the Roman Mass in Gaul and in the Mozarabic Mass of Spain. The Greek Church does not honor him, but he is commemorated in the Russian Church on the 15th of June. His festival is celebrated on the 28th of August, in accordance with the listing in the Roman Martyrology, and the Augustinian's keep his feast day as a double minor of the first class. He is the patron saint of theologians, printers, and brewers, and he is invoked against sore eyes, primarily among the Germanic Catholic States, but medical historians make no specific mention of this.

His impulsive nature as a youth led him, according to the various compilers, into an active life of vice, and it is considered that, in religion, he also went astray; however, from having been Hearer in the Manichaean sect, he ultimately proceeded to Rome and, thence, to Milan to teach rhetoric. The successive study of

Neo-Platonic writings, the summons of Saint Ambrose, and the Epistles of Saint Paul served to bring him nearer to the Church. His conversion is related very graphically in his "Confessions." After his baptism on Easter, in 387, and after a life replete with so many moral and intellectual errors, he began to live the life of a saint. He returned to Africa, was ordained a priest and, then, appointed preacher at the Church of Hippo Regius in 391 A.D. He was elected Bishop of Hippo in 395 and died there on the 28th of August, 430.

The significance of Saint Augustine's name is similar to that of the other saints who have been discussed, and the ocular implications are identical. This saint, however, while credited with many miracles of a common type as well as some special types, receives no mention in the available sources with reference to the performance of miraculous cures of eyes in ill health; but he has been represented in ecclesiastical art in association with Saint Lucy and, questionably, with Saint Clair (fig. 3). Saint Augustine's life is well documented, and it may be for this reason alone that there exists little in the way of hagiographic legends concerning him, but it seems more acceptable that this lack is sequential to his intellectual stature and to the austerity that permitted little, if any, romantic appeal.

COMMENT

The almost universal need in times of stress for assistance greater than that commandable by the average person from within himself has eventuated through the ages in the evolution of a common,

basic, supernaturalistic zenith, the form of which in the main has retained its familiar essentials from era to era but whose outward embellishments have varied with the dictates of the changing environmental forces whether antiquarian, pagan, or Christian. The interpretation of this known reliance in a higher power, but less than that of the Almighty, necessarily is expressed by each individual in terms of his own ambitions and endeavors; however, it should be the concern of those who administer to his biologic and spiritual requirements, real or apparent, not only to appreciate understandingly the factors productive of bodily ill health but, also, the equally important, more involved personality components that determine individual reactions and attitudes toward dysfunction and afflictions.

Faith in a belief, as one of these components, particularly requires sympathetic evaluation. It is not advocated that this faith be recommended as an agent of healing, whether by implication or by direction, but passively it may be utilized beneficially to promote an increased sense of well-being. If the practitioner is at all familiar with the basis of the beliefs encountered, and these are found so often among the members of our still unassimilated racial population groups, his therapeutic endeavors will undergo no deterioration if he does not deprecate the known but quiet need of the many for the supportive spiritual comfort that derives from a belief in the intercessory powers of the saintly martyrs.

60 East Seventy-fifth Street.

OCULAR THERAPY WITH PENICILLIN USED TOPICALLY, INTRAOCULARLY, AND SYSTEMICALLY

WITH CASE REPORTS

CONRAD A. MIETUS, CAPT. (MC), A.U.S.

The use of penicillin in the Brooke General Hospital since August, 1943, has shown the wisdom of following certain standard procedures. The following of these general procedures, as originally laid down by the director of penicillin therapy, Lt. Col. Richard B. Grant, Jr. (MC), has had the advantage of allowing the entire staff of the Brooke General Hospital properly to evaluate the results of the drug's use; the value of a director has resided in the fact that a stable drug has been used under standardized procedures. To have worked with a potentially unstable drug such as penicillin, which varies as it does in its potency, would have led to poor results in cases where the need for it was demanding and trying. Supervision overcame this factor.

With a penicillin of known strength, freshly prepared, and potency secured by keeping the solutions in a refrigerator, and checked against culture plates of known bacterial strength, the following procedures were followed and illustrate three modes of administration in ocular conditions; namely, (1) topically, (2) intraocularly, and (3) systemically or intramuscularly. It should be mentioned that penicillin therapy was limited to the most severe conditions. Intravenous therapy, reserved for the most acute of cases, was not resorted to, for in the words of Florey¹ "It is like pouring water down a basin with the plug out."

The following cases from Brooke General Hospital were followed by various members of the ophthalmologic staff:

TOPICAL USE OF PENICILLIN

CASE 1. A private from a cavalry post, aged 23 years, colored, reported that he

had been injured on January 16, 1944, when a beer bottle struck him in the face. He was immediately taken to his station hospital, where his injuries were listed as: (1) traumatic rupture of the left eyeball; (2) lacerated wounds of both upper lids, severe, and also of the left lower lid; (3) lacerated wound of the dorsum of the nose, mild; (4) lacerated wound of the sclera of the right eye, severe; (5) lacerated wound of the upper lip. The lacerations were all sutured with silk, except those involving the left eyeball, which was not repaired because of its severity. On January 17, 1944, the patient was transferred by ambulance to the Brooke General Hospital.

Physical examination on admission to Brooke General Hospital: The patient was in no evident pain; both eyes were bandaged, and the multiple lacerations of the face were well approximated. *Ophthalmic examination*: The lids could be opened, but were edematous. Visual acuity in the right eye sufficed only for finger counting at nine feet; the left eye was blind.

Right eye. None of the lid lacerations involved the entire thickness of the lid. Inspection showed that the laceration of the conjunctiva and sclera in the lower nasal quadrant was three-quarters inch long, running like a crescent three-eighths inch from the limbus down toward the cul-de-sac. Both conjunctiva and sclera were sutured together by three silk sutures in such manner that there was pouting and distortion of this segment of the globe anteriorly; discharge of a mucopurulent nature was present at the suture line. The cornea bore a thin, straight laceration, three-eighths inch long, run-

ning 3 mm. vertically down from the limbus at the 1-o'clock position. Moderate ciliary congestion was present. The anterior chamber was normal in depth; the pupil, dilated, did not react to light; the iris indicated no pathologic change; no prolapse was evident; a cortical opacity was observed in the upper half of the lens. The fundus could not be seen. Tension was normal by finger palpation. The slitlamp was not used, since this was a bed patient.

Left eye. None of the lid lacerations involved the entire thickness of the lid. The external canthus bore a large laceration, which curved down and out, enlarging the palpebral fissure. The globe was hopelessly ruined by three lacerations and was collapsed.

Progress and Treatment. A stimulating dose of tetanus toxoid, 0.5 c.c., was administered subcutaneously. A smear from the site of the laceration showed no organisms. One minim of 3-percent atropine-sulfate solution was instilled into the right eye twice daily. With the left eye destroyed and the right eye endangered by a corneal laceration, a traumatic cataract, and a severe scleral laceration, all efforts were directed to saving this eye. Accordingly, a fresh solution of penicillin was obtained for local therapy; this solution was made biweekly in the strength of 250 units of penicillin per cubic centimeter dissolved in an isotonic solution of sodium chloride; two drops were instilled into the right eye every 30 minutes, day and night, for 21 days. Between treatments sterile 4 by 4 pads were kept over the right eye at all times, in this manner securing a wet dressing of penicillin solution. The left eye was treated twice daily with 20-percent silver protein mild instillations.

On January 20, 1944, the right eye had vision estimated at finger counting at five feet; the ciliary injection was less in

amount. The tactile tension remained normal. Observation of the lens showed that its pathologic change had fortunately not advanced; the scleral laceration still appeared dangerous, with its pouting edges and the overlying mucopurulent exudate.

On the following day, enucleation of the left eye was performed, with implantation of glass ball, under intravenous sodium-pentothal anesthesia. Recovery was uneventful.

On January 22d, it was decided that the silk sutures of the right eye should not be removed, because of the danger of opening the scleral laceration. The site of the laceration showed much less exudate. Penicillin therapy was continued by topical instillation. The blood Wassermann test was reported positive on this date and in consultation a diagnosis of syphilis was made, late and latent, noninfectious.

On January 23d, vision in the right eye remained at finger counting and was improved slightly by lifting the head up and to the left. The pathologic change in the lens had fortunately not proceeded to complete opacification. The laceration of the sclera had healed, but there remained a deformity of this area disturbing the normal contour. The silk sutures had separated and were removed from the lower cul-de-sac. The left socket showed complete healing.

On February 8th, after penicillin therapy had been administered locally for 21 days, no signs nor symptoms of infection of the right eye were present. The soldier was therefore transferred to the Valley Forge General Hospital, an ophthalmic center, for further surgery and the learning of Braille.

Comment. In the writer's opinion, the instillation of penicillin into the right eye prevented further spread of infection through the scleral laceration. It may be argued that no organism was found by

smear; this is true. It may also be argued that the exudate was the normal response to tissue necrosis, produced by the sutures; however, the changes observed in the exudate and its gradual change to a mucopurulent nature in 48 hours and then its gradual decrease made us feel that penicillin was a definite help in preserving this one eye. The systemic use of penicillin in this case would be contraindicated, as previous writers have definitely shown that intramuscular penicillin is not excreted into the tears.^{2,3}

CASE 2. An infantry sergeant, 35 years old, white, was admitted to the Brooke General Hospital on October 5, 1943, with the complaint of severe, burning pain in both eyes of one week's duration. He had been treated at the eye clinic as an out-patient for one week with no relief. On hospital admission, the results of the general physical examination were negative.

Ophthalmic examination. Both eyes showed marked congestion of the entire ocular conjunctiva, most evident in the bulbar portion. Strings of pus were present in the cul-de-sacs. Fluorescein instillations showed no ulceration of the cornea. Vision was 20/20, J2-13 bilaterally. A culture and smear were taken; both showed a nonhemolytic *Staphylococcus aureus*. For the following 10 days, various treatments were tried without improvement. On October 15th, minute ulcers of the corneas had developed; these were superficial and involved the periphery of the corneas. Atropine and hot packs were started. On the following day, the condition had involved more areas of the corneas. The illness had now lasted 17 days. Penicillin topical therapy was started; the solution in the strength of 250 units per cubic centimeter was instilled into each eye every half hour, day and night; between treatments the eyes were kept bandaged.

Further progress. On the 18th of October, definite improvement was observed. The ulcers had not extended in size or number, and there was less discomfort and much less conjunctival secretion. Two days later, there was only faint corneal staining, with but little secretion from the conjunctivas. Subjective improvement also was evident. On October 22d the ulcers were healed, as evidenced by no staining of the corneas with fluorescein; all secretion was now absent. On October 23d, penicillin therapy was discontinued. Vision was 20/20 bilaterally.

Comment. Rapid relief of pain and resolution of inflammation without any harmful effects were produced in this case, in which *Staphylococcus aureus* was found. This would be expected as the staphylococci are one of a group especially susceptible to penicillin. Other writers³⁻⁶ have reported its efficacy in conjunctival or corneal lesions.

INTRAOCULAR USE OF PENICILLIN

A private from a cavalry unit, aged 31 years, colored, gave the history of having injured his left eye with baling wire while loosening a bale of hay on September 23, 1943, at 4:00 p.m. He presented himself the next day to the eye clinic of his station hospital, and the notes of the chart read that, "the conjunctiva was injected; the cornea was perforated in a curvilinear manner for 4 mm. at the 3-o'clock position near the limbus; iris protruding." An iridectomy under local cocaine anesthesia was performed on that date. The progress notes from September 24th to October 4th revealed that the vision in the left eye was light perception, and in the right eye 20/15. On October 4th, the cornea of the left eye was described as "foggy" with some injection of the conjunctiva. On the following day, the soldier was transferred to Brooke General Hospital. Admission examination revealed the pres-

ence of much ciliary congestion in the left eye; the tension was normal, but the globe was very tender; the pupil was small and deformed as the iris was incarcerated in the wound at the limbus at the 3-o'clock position. The general physical examination was negative. Laboratory reports showed erythrocytes 4,100,000; leucocytes 7,700; hemoglobin 80 percent; polymorphonuclears 50 percent; lymphocytes 50 percent; clotting time 5 minutes; and bleeding time 2 minutes, 30 seconds. The urinalysis showed many white cells; no urethral discharge was present. The Wassermann test was negative as was the Kahn test. On the 8th of October, an iridectomy was performed with a conjunctival flap, under intravenous sodium-pentothal anesthesia.

Progress notes and subsequent therapy. On the third postoperative day the left eye was comfortable; tactile tension normal. Atropine was prescribed, to be instilled twice a day.

October 16, 1943. Tension in left eye was normal; the corneal edema less; the eye generally was progressing nicely. The sutures were removed from the conjunctival flap.

October 20, 1943. Tactile tension was normal, but much ciliary congestion was present. Although the patient did not complain much, it was evident from observation that there was constant discomfort. The cornea was edematous. A dose of 25 million organisms of typhoid vaccine was injected intravenously.

October 25, 1943. The eye remained the same; it was totally blind.

November 4, 1943. More pain was present in the left eye, with much ciliary congestion. There were many cells in the anterior chamber and heavy deposits on Descemet's membrane; the dose of typhoid vaccine intravenously was repeated. Two ophthalmologists agreed that enucleation would eventually be necessary.

November 5, 1943. Examination on this

date showed vision, O.D. 20/20, J1 at 13"; O.S., nil for distance and near. Ciliary congestion was great. The cornea of the left eye was clear, but its posterior surface contained very many deposits, which could easily be seen macroscopically, and the deposits formed a rather bizarre picture, simulating a culture growth on the posterior surface of the cornea. There was no hypopyon, however. With the slitlamp, the iris details could not be seen owing to the thick deposit. The fundus, of course, could not be seen, even with the binocular ophthalmoscope. It was recommended that a paracentesis of the anterior chamber be performed with an attempt to irrigate the deposits with penicillin. The operation was performed under sodium-pentothal intravenous anesthesia. The left eye was fixed with fixation forceps. A sharp, 23-gauge needle, one inch long, attached to a tuberculin syringe was inserted into the anterior chamber at the limbus at about the 2-o'clock position in such manner as to lie over the iris and still be away from the anterior lens surface; withdrawal of the barrel was done slowly, until 0.25 c.c. of the aqueous was withdrawn. Collapse of the anterior chamber was quite evident at this point. The syringe was detached carefully from the needle and another syringe, containing 250 units of penicillin per cubic centimeter, was attached to the needle and 0.25 c.c. was injected into the anterior chamber. The latter re-formed, and it was observed that the deposits on the posterior surface were swept off by the inflowing penicillin. The needle was withdrawn and the eye bandaged. A culture of the aqueous was made; also, some was injected into the anterior chamber of a rabbit's eye in the hope of finding a causative organism, but both of these cultures were reported negative after 48 hours.

November 13, 1943. The first postoperative dressing showed that the eye was white! This unexpected result, with

subjective comfort, was pleasing. There was no ciliary congestion. The cornea was clear; the anterior chamber was reformed; the iris details could be seen, and a few individual deposits were present on the anterior surface of the lens. However, with clearing of the anterior chamber, a clear view of the vitreous was possible and an object, moving with the movement of the globe, was seen. This, apparently was a massive detachment of the retina and accounted for the blindness of this eye.

November 15, 1943. A thorough intraocular examination was made on this date, and the diagnosis of massive retinal detachment was verified. Slight ciliary congestion was present.

November 17, 1943. The eye was not so red, and the tension remained above normal.

November 24, 1943. The patient was discharged to limited service with a preserved globe and a quiet eye. The tension was normal, vision nil.

Comment. It is interesting to review the hospital confinement in this case. Immediately after his penetrating eyeball injury, the patient was hospitalized for a period of 10 days at his station hospital; at the general hospital he had spent five weeks up to the time of operation. After the intraocular injection of penicillin, the eye became white in 48 hours, and the soldier was discharged from the hospital 11 days later. It is believed that the injection of diluted penicillin solution into the anterior chamber definitely saved this eyeball, although vision remained nil.

SYSTEMIC USE OF PENICILLIN

An aviation student, white, 25 years of age, was transferred to Brooke General Hospital on March 24, 1944, from a distant station hospital. The pertinent history stated that "while he was on duty in a skeet tower at his airbase, he received an injury to the left eye, caused by a

stray pellet from a skeet gun (12-gauge with no. 8 shot), on the 21st of March, 1944, at about 2:30 p.m." A complete physical examination was negative except for the injury to the left eye. The vision in this eye was down to perception of hand movements. There was a round perforation of the left eyeball, 4 mm. below the inferior border of the limbus at the 5-o'clock position. No vitreous was presenting. Atropine was instilled at this time and a dressing applied. On March 22d, ophthalmologic examination was made: "inferiorly toward the 6-o'clock position is a vague, rounded mass, which may be the foreign body, or a localized vitreous hemorrhage, caused by the impact. Pupil is only slightly dilated. There is marked conjunctival edema, laterally. The vision today is finger counting." A radiologic report on this date stated: "there is seen a small metallic, foreign body in the left orbit in the left lower outer quadrant; on the lateral view it was found to be resting well in the orbit, but had not penetrated the cranium or sphenoid sinus."

On admission to Brooke General Hospital, March 24, 1944, the ophthalmologic examination showed the vision to be: O.D. 20/15—, J2 at 13"; O.S. light perception could not count fingers at 10 inches. The finger tension was found to be normal in both eyes. The right eye was normal throughout.

The left eye showed marked ciliary congestion. The site of the perforation was still evident in the area mentioned. Slitlamp examination revealed an increased flare of the aqueous; there were no keratic precipitates on the posterior surface of the cornea. No opacity was seen in the lens. With the ophthalmoscope, a dull, red reflex was observed, and many large vitreous floaters; the lower half of the vitreous was completely dark and nothing would be seen. Localization of the foreign body by X ray was performed with the Sweet localizer. This

revealed the presence of a spherical foreign body, 2 mm. in diameter, 34 mm. behind the cornea, 9 mm. below the horizontal plane, and 5.5 mm. to the nasal side of the sagittal line.

Laboratory work on admission showed: red blood cells, 4,360,000; hemoglobin, 80 percent, white blood cells, 7,950; polymorphonuclears, 66; lymphocytes, 22; mononuclears, 8; eosinophiles, 4. Urinalysis was completely negative. Sedimentation rate, 0-2-9-18 mm. in one (1) hour; hematocrit, 41; plasma protein, 6.8 gm. per 100 c.c. Kahn, negative; coagulation time, 3'15"; bleeding time 1'45".

Progress. March 25, 1944. The left eyeball was intensely injected; the vision remained at light perception. The patient this morning stated that for the first time the left eye was paining him. The pupil was well dilated. Blood was seen in the lower part of the anterior chamber, which was very deep. The media were definitely more cloudy today. One cubic centimeter of tetanus toxoid was given as a stimulating dose. An injection of 25 million organisms of typhoid vaccine was given intravenously for its foreign-protein effect. It was evident then, from the reports given, that there was a double perforation of the eyeball, caused by the pellet in its entrance and exit at 34 mm. from the cornea.

March 27, 1944. Subjectively, the patient was complaining of more pain in the eye. There was no edema of the lids, but there appeared to be more lacrimation. Vision was reduced to light perception. No fundus reflex was obtainable. The possibility of detached retina was being borne in mind; also the fact that traumatic injury was created at the point of exit of the pellet and possibly also behind the globe. Foreign protein was again administered in the form of 25 million organisms of typhoid vaccine intravenously.

March 29, 1944. The patient was requesting frequently, doses of medicine for

pain in the eye. Edema of the upper lid was present.

March 30, 1944. Penicillin solution was injected on this date into the anterior chamber of the left eye, with the patient under intravenous sodium-pentothal anesthesia. The white count was increased at this time to 10,050 with 66 percent polymorphonuclears. The same penicillin-injection technique was used as in case 2. In this case, however, 0.5 c.c. of aqueous was withdrawn, for, as mentioned previously, the anterior chamber was very deep, and 0.5 c.c. penicillin solution was injected.

March 31, 1944. Edema of the lids was less than on the previous day; subjectively, the patient has not complained of so much pain as previously.

April 1, 1944. Examination of the eye showed that there was slight edema of the left upper lid, also the same amount of congestion as previously (increased possibly by fixation forceps and needle trauma). The cornea was clear, the anterior chamber was very deep, with no hypopyon or blood; the pupil was dilated. In order to give this eye every possible chance, penicillin was ordered to be given intramuscularly to combat the endophthalmitis and possible retrobulbar infection. An intravenous injection of 40 million organisms of typhoid vaccine was also to be administered, for the previous administrations did not raise the mouth temperature beyond 100.8°. A smear from the aqueous was reported: "No bacteria are found, and a 48-hour culture of the aqueous shows no growth."

Therapy consisted of instilling one drop of 3-percent atropine-sulfate solution into the left eye once daily and hot compresses to the eye three times daily. The intramuscular or systemic use of penicillin was started on April 1st by injecting 25,000 units every three hours day and night, and this was continued for 42 days.

By the 4th of April, the patient was

more comfortable and he stated that he could see light and shadows temporally. The ophthalmoscope still revealed no retinal reflex. The edema of the lid had disappeared completely. The white blood count on this date was 8,300; hemoglobin, 80 percent; the differential count was 68 percent polymorphonuclears, 31 lymphocytes, and 1 monocyte. The plasma protein was 6.6 percent.

On May 12th the penicillin therapy was discontinued and the condition of the eye was as follows: Vision remained at light perception; a faint ciliary flush persisted; the cornea was clear; there were a deep anterior chamber, a slight fundal reflex superiorly and nasally, and a grayish mass, slightly movable, could be seen above, which undoubtedly was a detached retina.

When intramuscular injections must be repeated frequently, it is important to keep the volume as low as possible in order to avoid local discomfort at the site of injection—the usual practice has been to employ a concentration of 5,000 units per cubic centimeter of isotonic solution of sodium chloride.

It is also well to remember to give large initial doses of penicillin, because bacteria may become "penicillin fast" with small doses. The amount to be given will vary with the individual case, as many as 6 million units having been given a month in some cases; it will vary with the type of severity of infection. It is suggested that the adequate dosage, although not

clearly defined, be kept around 200,000 units daily. The intramuscular route is the usual route⁵ by which this drug is administered. It should be given into the muscle and not into the subcutaneous tissue; its use in ocular conditions is similar to that adopted in other systemic infections.

Comment. This eyeball was definitely saved by the systemic use of penicillin. Edema of the upper lid is in itself always a serious sign whether it denotes an endophthalmitis or an orbital cellulitis. The intramuscular use in this case was prolonged, perhaps, but considering the seriousness of the condition, was justified. We have had no untoward reaction from the use of penicillin in our eye cases; urticaria, transient azotemia and eosinophilia were watched for.

SUMMARY

1. Penicillin is a wonderful new therapeutic agent which can safely be added to the armamentarium of ophthalmologists.

2. Penicillin can be utilized in the three ways demonstrated in the foregoing case reports.

3. The use of penicillin by injection into the anterior chamber offers promise of beneficial results, and this mode of therapy warrants further investigation.

The writer is indebted to Lt. Col. Richard B. Grant, Jr. (MC), A.U.S., Director of Penicillin Therapy, for his ready advice in the treatment of these cases.

SEROLOGIC STUDIES IN ACUTE EYE DISEASES*

CLAUDE C. GRAY, M.D., AND WILLIAM A. MOOR, B.A.

Saint Louis

It has been stated that the sera of patients affected by an acute febrile illness as, for example, pneumonia, tonsillitis, sinusitis, and acute upper respiratory infections, will produce a swelling of the capsule of Type XXVII pneumococcus.¹

It was decided to apply this simple test to the sera of patients who had various eye lesions with or without febrile reactions. If it were possible to demonstrate the nonspecific capsule (N.S.C.S.) swelling, one might postulate that the etiology of the ocular pathology was due to a hidden focus of infection.

It is well known that the pneumococcus contains three different chemical constituents; namely, (1) type-specific polysaccharide A, (2) the nontype-specific nucleo-protein B, and (3) the somatic C fraction. The last named of these, according to Tillett, Goebel, and Avery² is different chemically and immunologically from the first two, and is sometimes known as a nonspecific carbohydrate.

By using this nonspecific carbohydrate in concentrated form, R. Ash³ concluded that precipitants for the pneumococcus were present not only in pneumococcic infections, but also in illnesses due to the gram-negative as well as to the gram-positive organisms. Syphilitic infections did not produce this phenomenon, nor did it generally appear in tuberculous disease, or, if it did, only in small amounts.

Normally, the sera of healthy humans do not produce capsular swelling, judging from the work of G. Lofstrom¹ in 1939, who stated that the sera of 120 healthy recruits in the Swedish army did not produce the reaction with the pneumococcus;

but he found that it was positive in one third of 157 soldiers who had an upper-respiratory infection, and that this percentage was independent of the elevation of the body temperature. The reaction became negative between the sixth and the twelfth day in 12 cases running a smooth course. But the cases either ended fatally or developed complications in others wherein the reaction remained positive.

In an attempt to correlate the foregoing observations with the responses to be found in acute inflammatory eye conditions, 5 to 10 c.c. of blood were collected from each of the 16 patients tabulated. Sera were separated and stored in the refrigerator until all were on hand. The routine Neufeld type of pneumococcus typing reaction was done with all sera. The pneumococcus Type XXVII used was obtained from the American Type Culture Collection and when received had a very small capsule. However no animal passage nor other method of enhancing capsule size was attempted, as it was felt that sufficient material was present for observation of swelling. Observations of mixtures to determine swelling were made (1) at once, (2) after four hours at room temperature, and (3) after overnight storage in the refrigerator.

Case 13 not only exhibited swelling of the capsule, but also microscopic agglutination. The Type II pneumococcus that was recovered from the tonsillar material probably represents only the predominant type, and Type XXVII may have been present, but missed.

In using this test on 16 cases exhibiting acute inflammatory eye lesions, it was found positive in one of seven patients with iritis, positive in one of four cases

* From the Department of Ophthalmology, Washington University, and the Oscar Johnson Institute.

16	L.H.	Optic neuritis, O.U.	22 days	43	F	W	0	none	—	Probably due to hair dye

with chorioretinitis. This test was negative in two cases of corneal abscess, one case of dendritic ulcer of the cornea, and one case of optic neuritis. Out of this group, the nonspecific capsular swelling was not present in three cases in which the patient had received artificial fever from the use of intravenous paratyphoid-typhoid vaccine. The two cases which showed a positive reaction were as follows:

Case 6. R. W., a white man, aged 28 years, entered the hospital on the ninth day of his illness with an acute uniocular plastic iridocyclitis. He gave a history of an acute Neisserian urethritis eight years

ago, followed in a few months by an acute arthritis of the right knee. During his hospitalization the complement fixation for gonorrhea was positive, but the prostate was negative for pus. X-ray studies of teeth and chest were negative. Kahn, urine, and brucella agglutination tests were negative. Diagnosis in this case was gonococcal iritis. The patient's serum gave a positive reaction to Type XXVII pneumococcus. Treatment was successful with sulfathiazole and the Kettering hypertherm. It has not been possible to obtain a follow-up reaction of his blood.

Case 13. G. S., a white woman, aged 21 years, had an extensive chorioretinitis

and optic neuritis with an eccentric vision of 6/60. She was given a four-day course of sulfadiazine. An adequate blood level was obtained, but this was stopped because of nausea and vomiting. A total of 400 million paratyphoid-typhoid vaccine was given intravenously on four separate days, but the choroiditis continued to advance. She showed a moderate amount of keratitic precipitates and a few cells in the anterior chamber. X-ray studies of her teeth and chest were negative. Cervical examination by a gynecologist was negative. Agglutination for brucellosis, Kahn, typhoid, tularemia, and urine tests were entirely negative. The otolaryngologist thought her sinuses were normal and that her tonsils were not involved enough to warrant removal unless no other cause could be found. On the thirty-fifth day of her illness, just the day prior to the tonsillectomy, the serum produced a capsular swelling of Type XXVII pneumococcus with microscopic agglutination. One week postoperatively the eye lesions (uniocular) were the same, but the N.S.C.S. test was negative. Two weeks postoperatively the serum still remained negative and the eye lesions had improved in that there were no more hemorrhages, less retinal edema, no cells in the anterior chamber, and only a few mutton-fat K.P. remained. It was interesting to note that her tonsils cultured Type II pneumococcus, streptococcus, and staphylococcus. Her vision to date remains 6/60 eccentrically.

Four patients in this group, thought to have tuberculous uveitis, showed no non-

specific capsular swelling. This tends to confirm the work of Ash³ in tuberculous disease, who used the concentrated C fraction.

It is realized that only a few cases are reported here and for this reaction to be of further significance a greater number of cases should be studied. It is not an expression of wishful thinking to state that if a serum produces a positive reaction, the etiology for the eye lesion is likely to be found in a focus harboring the causative organism.

Just as Lofstrom⁴ claims that one may use his test (nonspecific capsular swelling of pneumococcus) in differentiating a bacterial meningitis from a virus meningitis, in that it is positive in the former and negative in the latter, an ophthalmologist might differentiate an iridocyclitis or choroiditis due to a bacterial agency or any other etiologic agent as an allergin or a virus.

SUMMARY

1. The sera of 16 eye patients were used in the manner of the Neufeld test to determine the presence of an agency that would produce a nonspecific capsular swelling of Type XXVII pneumococcus.
 2. Two cases showed a positive reaction.
 3. The etiology of these two cases was determined to be an organism in the gram-negative or the gram-positive groups.
 4. After removal of the cause of the choroiditis, the test became negative.

NOTES, CASES, INSTRUMENTS

INTRAOCULAR INJECTION OF PENICILLIN IN OCULAR INFECTIONS

PRELIMINARY REPORT

V. LA ROCCA, M.D.

New York

The purpose of the present paper is to report the comparative results obtained in the treatment of two cases of corneal ulcers with hypopyon, one having been treated with intraocular and subconjunctival injections of sodium penicillin, the other solely by subconjunctival injections of sodium penicillin.

The information I was able to gather before I started the penicillin therapy was meager, especially in regard to the concentration of this drug and to the best route of administration, investigations and reports on this subject being at the time almost nil. The two common methods of administration of penicillin, intravenous and intramuscular, were discarded from the beginning, for it was thought that a direct application would be more effective and beneficial than the intravenous and intramuscular injections, which generally are given at very frequent intervals.

In case 1 an injection into the anterior chamber of 50 Oxford units of sodium penicillin was followed by subconjunctival injections, whereas in case 2 only subconjunctival injections were used. Both cases were complicated by other pathologic changes; namely cataract in the first and absolute glaucoma in the second.

REPORT OF CASES

Case 1. M. F., a man, aged 70 years, was first seen in my office on April 17, 1944, because of an ulcer of the cornea

of the right eye. Vision, O.D., was perception of hand movements; O.S., 20/70. For about eight days he had been treated by a private physician who had cauterized the ulcer and had advised atropine instillations, sulfathiazole ointment, and hot compresses, but with no apparent results.

Examination showed an infiltration of the cornea of the right eye from the central and nasal sector to the lower part, extending about 4 mm., a severe conjunctivitis, and perikeratitic injection. The rest of the cornea was hazy. The slitlamp examination showed an enormous number of cells in the aqueous and a small half-moon of exudates in the lower part of the anterior chamber. The pupil was irregularly dilated with some posterior synechiae, and there was a cataractous lens. The tension was normal to touch, and the eye very painful, particularly in the ciliary region. The patient complained of severe frontal headaches.

Sulfatherapy was started internally and continued for about three weeks. Besides the local treatments with atropine, local applications of sulfathiazole ointment 5 percent, applications of antiflogistine, ultraviolet irradiations, cauterization, and other measures were used. The only possible foci of infection were eliminated by the removal of several teeth which showed apical abscesses. The smear examination was negative.

On April 22d the condition of the eye was worse; namely, pus in the anterior chamber was filling about one fourth the cavity, the infiltration of the cornea had become very deep, and the general signs and symptoms were gradually becoming more severe.

Typhoid therapy was started, with an initial dose of 15 million triplo-typhoid bacilli intravenously, which caused a fe-

ver of 104°F. At different intervals the typhoid therapy was repeated, with increasing doses, while the local treatment was continued and the sulfatherapy repeated. On May 9th the patient was admitted to the New York Eye and Ear Infirmary. Inasmuch as a fibrinous and cellular exudate was filling almost one half of the anterior chamber, a paracentesis was done with a keratome inci-

either paracentesis or the withdrawing of aqueous, 0.05 c.c. of sodium penicillin, containing 50 Oxford units, was forced into the anterior chamber with a tuberculin syringe. Another 100 units were injected subconjunctivally. Examination of the eye on the following day showed the complete disappearance of the hypopyon; there was a mild chemosis of the bulbar conjunctiva. The patient stated that for

Figs. 1 and 2 (La Rocca). Corneal ulcer, right eye. Fig. 1, case 1, infiltration of the cornea with hypopyon. Fig. 2, case 1, after treatment with penicillin.

sion of the upper part of the limbus, and aqueous was aspirated with a syringe and sent to the laboratory for smear and culture; this was later found to be negative. Several attempts were made to cleanse the anterior chamber of the fibrinous exudate by lavage (repeated irrigations with a saline solution), but very little material was washed out, the mass being strongly adherent to the iris mesh. More irrigations were made with a fresh solution of 5-percent sodium sulfathiazole, and an atropine and sulfa dressing was applied. For the next two days the amount of pus was apparently reduced, but soon the condition returned to the former stage so that as a last resort, I decided to start some sort of penicillin therapy.

On May 15th the patient was returned to the operating room where without

the first time since his illness he had been able to rest at night. The subconjunctival injections were repeated daily at the bedside following instillations of a 4-percent cocaine solution for 10 minutes, the patient's only complaint being a sharp pain upon introduction of the penicillin which lasted only a few minutes.

The number of units injected was gradually increased to 1,000, and on May 26th the cornea for the first time did not stain with fluorescein. The patient had been discharged from the hospital on May 20th and the remaining injections were given in my office. As figure 2 shows, a corneal leukoma and a diffuse haziness of the cornea were still present as a result of the long-standing infection.

Case 2. F. D., a man aged 58 years, was first seen in my office for the present

illness on April 27, 1944. The right eye was affected with absolute glaucoma: T = 3 plus. Vision was O.D. no light perception; O.S. 20/200; with correction 20/30. There was an ulcer of the cornea in the glaucomatous eye, with an infiltration of the central area and a diffuse disepithelization of the cornea; numerous K.P. and a hypopyon were in the lower part of the anterior chamber. The report of the smear of the conjunctiva was "Occasional polymorphonuclear leukocytes, no eosinophiles nor inclusion bodies, nor bacteria. The culture revealed diphtheroid bacilli; the Wassermann test was negative, and there were no apparent foci of infection. The treatment followed was similar to that in case 1; namely, sulfa drugs, typhoid therapy, local treatments, ultraviolet irradiations—with the same negative results.

On May 15th when I was able to obtain 100,000 units of penicillin for case 1, some of the same solution was injected in the lower part of this patient's bulbar conjunctiva, at daily intervals.

He complained of sharp pains soon after the injection, lasting one or two minutes. The doses gradually reached the 1,000 units on May 24th and were continued daily in that amount to June 4th. The hypopyon disappeared very slowly from about May 22d, seven days after the first injection of penicillin, and the corneal ulcer for the first time did not stain on June 6th, 22 days after the beginning of the penicillin therapy.

SUMMARY AND COMMENT

Two cases of ulcer of the cornea with hypopyon are reported in which the elimination of focal infections, local treatments, sulfatherapy, fever therapy, and ultraviolet irradiations failed to produce results after almost one month of treatments. Penicillin therapy was begun, with striking success in one case in which the

penicillin was introduced directly into the anterior chamber and the treatment continued with subconjunctival injections; with more modest results in the other case, in which the penicillin was administered by subconjunctival injections alone.

In case 1 the hypopyon disappeared completely in less than 24 hours, and the ulcer healed after 11 days of further therapy. In the second case the hypopyon disappeared after 7 days and the ulcer healed after 22 days.

Although two cases are not enough from which one may draw conclusions of great importance, the results obtained point to the following facts:

1. The direct application of penicillin to the spot of infection is of greater therapeutic value than injections relatively near to it, such as subconjunctival injection.

2. The amount of penicillin required for the almost instantaneous disappearance of the hypopyon by intraocular injections is very small compared with the amount necessary by subconjunctival injections.

3. The use of penicillin by intraocular injection is not injurious to the eye, and the local reaction is negligible, whereas the pain and the conjunctival chemosis resulting from subconjunctival injections, although not serious, are somewhat annoying.

4. The handling of penicillin is not difficult. I made a mother solution of 10,000 Oxford units per c.c. which was kept at a temperature of 5°C. (which is supposed to be active for one month). From the mother solution, fresh solutions containing the amount needed were made for immediate injections.

The recommendation for the use of penicillin by intraocular injections is to be considered as an attempt to reach a better knowledge of the action of this

drug in ocular infections. It is fully realized that revisions of the dosage may be required as experience accumulates on this subject.

CONGENITAL CATARACT FOLLOWING RUBELLA IN THE MOTHER

REPORT OF A CASE

CHARLES A. PERERA, M.D.
New York

American ophthalmologists are indebted to Dr. Algernon B. Reese¹ for calling to their attention the occurrence of congenital cataract and other congenital anomalies in children born of a mother who had rubella during the first three months of pregnancy. This subject appeared in the Australian ophthalmologic literature in 1942 and 1943, from the pens of N. M. Gregg² and a group of colleagues.³ Dr. Reese reviewed these two papers and added three cases of his own.

The findings in the cases reported included: (1) congenital cataract in 94 patients, of which 20 had the condition unilaterally; (2) microphthalmia; (3) intolerance to atropine; (4) congenital cardiac condition, diagnosed as patent ductus arteriosus in most instances; (5) mental retardation; (6) microcephaly; (7) deaf-mutism; and (8) difficulty in feeding.

Since Dr. Reese presented this matter

before the staff of the Institute of Ophthalmology of Presbyterian Hospital, New York City, I have studied one case and encountered two others which are under the care of colleagues.

Case report. D. G., a girl, aged 4½ months, was referred to me on April 18, 1944, because of a white pupil of the right eye, which had been noticed for several weeks. The child had been under the care of Dr. Marguerite A. Schafer, of Hawthorne, New Jersey. The baby was born at term, but has been an extremely difficult feeding problem. At the age of eight weeks, she weighed no more than her birth weight (6¼ lbs.). She suffered from rickets and scurvy, and had a spontaneous hemorrhage into her left knee joint, with subsequent abscess formation. Her parents and her five-year-old sister had "German measles" when her mother was in her second month of pregnancy.

Physical examination revealed no abnormalities except a dense central cataract of the right eye, a congenital cardiac condition (probably patent ductus arteriosus), and malnutrition. The eyes were normal in size, with anterior chambers of the usual depth, and normal intraocular pressure.

The cataract of the right eye was needled on April 21, 1944, at the Institute of Ophthalmology. Absorption of the lens has been slow. Up to date, there has been no evidence of sensitivity to a daily instillation of 0.25-percent atropine sulfate in the right eye.

70 East Sixty-sixth Street.

CHEMOTHERAPY IN TREATMENT OF SYMPATHETIC OPHTHALMIA

CASE REPORT

ALBERT E. LONG, M.D.

Weston, West Virginia

It is not the purpose of this paper to speculate upon the etiology of sympathetic ophthalmia. In consideration of treatment of a disease so damaging to vision, however, it is well to recall that at least two, and possibly other factors are thought to be involved in its causation. It is generally conceded that allergy to uveal pigment constitutes one phase as demonstrated in the work of Elschnig,¹ Woods,² and by numerous subsequent observers. In addition there also seems to be an infective phase, possibly from an unknown virus or its toxin, or even possibly tuberculous, in that all the manifestations of this disease cannot be explained from an allergic standpoint alone.

Treatment of this syndrome has therefore been empiric in nature, with the exception of the use of uveal pigment injected hypodermically.³ The normal reaction of the body apparently consists of the development of immunity to the pigment, thus preventing further absorption from the injured area. The rationale of injection of pigment therapeutically is to raise the pigment-antibody content of the blood serum sufficiently to obtain immunologic balance. Susceptibility to sympathetic ophthalmia follows any failure to develop such immunity.

Foreign protein, chiefly typhoid vaccine,⁴ tuberculin,⁵ diphtheria antitoxin,⁵ and boiled milk,⁶ have been extensively used, and are most helpful in the management of the disease, although in no instance has it been claimed that eradication of the pathologic process has been

attained. Chemical treatment has for the most part been confined to the use of massive doses of salicylates⁷ or arsenicals, chiefly neosalvarsan.⁷ Symptomatic improvement has followed in many instances in which these drugs have been employed. Local treatment consists chiefly of the maintenance of full pupillary dilatation in order to prevent formation of synechiae. The attainment of this objective is frequently rendered difficult by the complication of increased tension, for relief of which repeated paracenteses may be done.

Although use of sulfonamides in this disease has generally been held to be futile, Gamble,⁸ in 1940, reported a case in which chemotherapy was employed during exacerbations, with very marked improvement. This author felt that the disease could occasionally be controlled enough to maintain useful vision without expectation of actual cure. However, at the death of his patient (from accidental causes), serial sections not only proved the disease to be sympathetic ophthalmia, but also indicated that considerable active pathologic change was present in an eye which appeared quiet clinically.

Thygeson,⁹ on the other hand, definitely stated that no improvement was noted in two cases of sympathetic ophthalmia treated by him with sulfathiazole and sulfadiazine.

CASE REPORT

A case of sympathetic ophthalmia is reported in which fair vision has been retained over the period observed, by the use of sulfonamides during periodic exacerbations, in conjunction with intravenous typhoid therapy and massive doses of salicylates.

C. P. was struck in the left eye, on February 7, 1941, presumably by a piece of rock. Site of wound was in the limbic area at about the 5-o'clock position and

* From the General Hospital of Weston, A. F. Lawson, Chief of Staff.

apparently penetrating. As the patient had very little pain at the time, no physician was consulted. Spontaneous healing of the wound apparently occurred, and except for moderate injection of the injured eye, the patient was symptom free for about two months. Following this, considerable pain developed in the eye and he noticed rapid loss of vision. As he lived in an isolated community, he did not consult a physician until April 22, 1941, when vision in the injured eye had failed completely and considerable blurring of vision had been noted in the right eye. He was referred to us chiefly for relief of the intense pain in the injured eye.

When first seen, the injured eye was entirely blind; intraocular tension was 76 mm. Hg (Schiötz). A small ciliary staphyloma of purplish hue and about 3 mm. in diameter was protruding at the limbus at the 5-o'clock position. The pupil was markedly constricted and irregular from annular posterior synechiae, and entirely occluded with dense white exudate, precluding ophthalmoscopic examination. The right eye was moderately injected and the pupil constricted, but no synechiae were present. There were numerous keratitic precipitates on Descemet's membrane, and many cells were floating in the anterior chamber, giving a typical aqueous flare. There was moderate ciliary tenderness. Intraocular pressure was 29 mm. Hg (Schiötz). On ophthalmoscopic examination a red reflex could be obtained, but no details of the fundus could be made out. Vision was reduced to light perception.

As the injured eye was exceedingly painful, and as there was no hope of restoration of vision, it was immediately enucleated. Treatment of the sympathizing eye was instituted by the use of intravenous typhoid therapy and massive doses of salicylates. The appearance of

the eye as well as vision improved slightly under this routine, only to return promptly to the original state. It was then decided to try sulfonamides (sulfathiazole orally), a concentration of approximately 5.5 mg. percent being maintained in the blood. Administration of the drug was continued for one week, with dramatic results, including clearing of most of the precipitates from Descemet's membrane and disappearance of the aqueous flare. Vision was 20/30 unaided. There have been nine acute exacerbations of the disease, lasting from one to three weeks during the subsequent two years the patient has been observed. Each attack has been controlled by the use of sulfathiazole, although the response has been more rapid on certain occasions than at others. There has been no elevation of tension and vision has been maintained at approximately 20/30. A few keratitic precipitates remain after each exacerbation and are the only evidence of the presence of the disease. Further hospitalization has been unnecessary.

SUMMARY

A case of sympathetic ophthalmia is reported in which chemotherapy was employed in conjunction with other therapeutic methods, after the apparent failure of the latter. Dramatic resolution of the inflammatory process was observed at each exacerbation, following use of the drug, although it was impossible to prevent its recurrence. Vision of 20/30 and an eye which is clinically fairly quiet has been maintained over a period of about two years. Although it is generally thought that chemotherapy is of no avail in any type of uveitis, it is possible that an occasional case of sympathetic ophthalmia may be controlled although not cured through its use.

TRICHO-EPITHELIOMA
OF EYELID

CASE REPORT*

JOHN E. L. KEYES, LT. COL. (MC),
A.U.S., AND FRANK B. QUEEN,
LT. COL. (MC), A.U.S.

Tricho-epitheliomata are somewhat rare nonulcerating, nonmetastasizing, often multiple, benign tumors of the skin, of limited growth. Histologically distinctive, clinically they are not distinguishable from many other benign tumors of the skin and dermal derivatives. They present an appearance, in common with tumors of the sweat and sebaceous glands, of small, slightly elevated, flat, pale or translucent, circular or slightly irregular hard tumors, frequently on or near the face.

Very few cases of this uncommon condition have been reported, possibly because the tumor, when uncomplicated, is not of major clinical importance. The authors recently encountered an example of tricho-epithelioma of unusual interest because of its location (on the palpebral margin of an eyelid) and its clinical appearance. A brief summary of this case is presented.

CASE REPORT

A white corporal, aged 21 years, reported to the eye clinic at Bushnell General Hospital on February 17, 1943. He complained of a small recurrent, painless, localized nodule bordering on the margin of the left upper eyelid. A tuft of material resembling blond hairs protruded from the swelling. The original nodule was first noticed about January, 1942, when a clump of blond hairs was observed among the cilia of the left upper eyelid. These unusual cilia increased in number and length. A small localized elevation of the skin of the eyelid developed concurrent with the abnormal cilia. The patient cut the strand of blond hair when it became noticeably longer than his normal cilia. The growth was never epilated.

Prompt recurrence of the growth occurred after its removal by curretting on or about September 15, 1942. Ulceration was never present. At no time was the growth of the hairy nodule rapid. Development, except for growth of the blond hair, was apparently stationary for two months before the patient reported to this clinic. There was no known etiologic factor. Neither this soldier, nor any member of his family, had a history of nodules on the face, forehead, eyelids, or nose. Complement fixation tests for syph-

* From the Department of Surgery, E.E.N.T. Section, and the Laboratory Service, Bushnell General Hospital.

ilis were negative. Complete physical examination revealed no other abnormality than the nodule in the left upper eyelid.

Examination of patient's left upper eyelid revealed a tuft of material resembling finely teased dental floss protruding from the lid margin. This material origi-

Fig. 1 (Keyes and Queen). A drawing of the tumor.

nated in a small localized firm subcuticular swelling. Viewed through a magnifying loupe, the strand of light-colored material was identified as immature hairs of varying lengths and sizes. The longest hair measured about 10 mm. The terminal one third of the strand of hair curved downward.

The tumor and attached cilia were extirpated by operation on March 17, 1943. The skin of the eyelid was split over the upper limit of the tumor. The skin was undermined and easily freed from the underlying nodule. The tumor was removed without trauma or rupture. Recovery was uneventful. Nine months after operation there was no evidence of recurrence.

PATHOLOGIC REPORT

Gross: The specimen consisted of a small round firm elongated piece of tissue (0.4 by 0.3 by 0.3 mm.) from which

a clump of very light brown hair protruded.

Microscopic: There was no evidence of a capsule nor of epithelial covering. The general appearance of the specimen was that of modified corium. The stroma varied in density in different parts of the specimen. One area consisted of firm fibrous tissue with a hyalin keloid appearance and very few cellular elements. Other areas contained many structures supported by a less dense, more normal-appearing connective-tissue stroma.

Each low-power field contained many immature hair follicles, some of which contained a partly developed hair stalk. The internal sheath of the hair contained keratin mingled with the cells of Henle's

Fig. 2 (Keyes and Queen). Histologic detail of a portion of the tumor nodule. Acc. No. 91883 U. S. Army Medical Museum.

and Henkle's layers. Occasionally a glass membrane was present. Many irregularly shaped masses of basal cells were noted. There was an effort at palisading of the basal layer of cells. Some of these cell masses were solid, suggestive of the appearance of Krompecher's carcinoma.

No prickle cells nor other cytologic evidence of malignancy was observed. Other cell masses contained cystic spaces in which keratinous material was concentrically arranged. Hair shafts were definitely present in some of these cystic spaces. The appearance of the hair follicles suggested a hamartomatous reaction, possibly based on lanugo or infantile hair follicles. Sebaceous glands and ducts of sweat glands were also present in the specimen. The blood supply was scant.

Col. J. E. Ash (MC), U.S.A., curator of the Army Medical Museum, reported on this specimen as follows: "I do not believe it is malignant, more of a nevoid lesion, some of the hair follicles being immature, of the lanugo type. I am not too fond of the term tricho-epithelioma, but it would seem to fit this tumor."

Diagnosis: Tricho-epithelioma, benign, of eyelid.

COMMENT

The term tricho-epithelioma is used in a histologic sense. The trichomatous nature of this solitary lesion was obvious

clinically and histologically. The presence of immature hair differentiated the growth clinically from the tumors of Brooke,¹ Jarisch,² and Fordyce.³ Reference is made to the articles of McDonagh⁴ and Traenkle⁵ for a discussion of the relationship of epithelioma adenoides cysticum, tricho-epithelioma, and basal-cell cancer.

A search of the available medical literature failed to reveal a report of a similar lesion on the margin of the eye lid.

Definite, clear-cut descriptions of tricho-epitheliomata are difficult to find. Many of the standard texts dealing with tumors do not mention the condition, as Boyd (*Surgical pathology*, ed. 5), Pack and Livingston (*Treatment of cancer and allied diseases*). Ewing (*Neoplastic diseases*, ed. 4), in his discussion of epidermal carcinoma, does not refer to tricho-epithelioma as such, though he does mention (p. 904) that "some basal cell tumors with compact groups of small elongated cells, or occasionally with adenoid characters, arise from the hair follicles."

ENDOPHTHALMITIS SUBSIDING AFTER TREATMENT WITH PENICILLIN*

MARTIN I. GREEN, M.D., AND

RAFAEL JAKOBOVITS, M.D.

San Francisco 9

The prognosis in cases of fully developed suppurative endophthalmitis is

*From Greens' Eye Hospital.

grave, and, as a rule, after all therapeutic measures to save the eye have failed, evisceration must be performed. Recently, however, the introduction of penicillin offers a new therapeutic approach in the treatment of many purulent ocular conditions, as may be illustrated by the following case.

History. A man, aged 70 years, was referred to the Greens' Eye Hospital on

March 22, 1944, because of inflammation of the left eye. Four years previously he had been examined by an ophthalmologist and it was found that the patient had an immature cataract in each eye. At that time the vision of the right eye was 20/30 and that of the left eye was 20/120. In April, 1940, an extracapsular cataract extraction was performed on the left eye. On the twelfth postoperative day an iris prolapse in the wound was discovered. It was cauterized several times with trichloroacetic acid, which caused it to shrink to a small bleb from which there was no seepage. Four days later the vision of the left eye with correction was found to be 20/20, and the patient was dismissed by his surgeon as cured. Three months later a cataract extraction was performed on the right eye. The postoperative course was uneventful and subsequent vision of the right eye with correction was 20/30.

On admission to the Hospital, on March 22, 1944, the patient stated that six weeks previously the left eye had become inflamed. A physician had given him some eye drops which failed to relieve the irritation. Two days prior to admission, as the discomfort increased, he again consulted his physician, who diagnosed the condition as keratoconjunctivitis and prescribed sulfathiazole ointment as well as sulfathiazole to be taken by mouth. However, as the vision of the left eye became progressively more blurred, and a slight hypopyon was noted, the patient was referred to the Hospital for diagnosis and further treatment.

Examination. On admission, the left eye showed marked circumcorneal injection. The cornea was cloudy, with deep infiltration in the center, and striation of the lamellae. A hypopyon projected 1 mm. into the anterior chamber. There was marked infiltration of the conjunctival flap at the 12-o'clock position. A yellowish reflex from the vitreous was

noted. Vision of the eye was reduced to light perception. Projection was faulty. A smear of the purulent contents of the cul-de-sac showed *Staphylococcus albus* of the nonhemolytic type. The diagnosis of endophthalmitis of the left eye was established.

Treatment and Course. The patient was hospitalized on March 22, 1944. On the first day treatment consisted of the local use of atropine ointment and sulfathiazole ointment, intravenous administration of sulfadiazine (70 c.c. of 5-percent sodium sulfadiazine solution in distilled water) and oral administration of sulfamerazine (15 grains). The condition of the eye did not improve, and the intraocular pressure increased to palpation.

On March 23d, the second hospital day, medication with penicillin was begun. The drug was administered in doses of 2 c.c. of a 10-percent solution (20,000 units) in normal saline solution, injected intramuscularly every three hours, day and night, successively, until a total of 22 injections (700,000 units) had been given in three days.

On March 25th the margin of the conjunctival flap was whitish. The cornea was still steamy, and fibrinous exudate was present in the anterior chamber. The iris was grayish and muddy in appearance, and some exudate could be noted on the anterior surface of the vitreous.

On March 26th the upper portion of the cornea appeared more transparent, and the exudative mass had decreased in size. The administration of penicillin was discontinued, and treatment with sulfamerazine, two tablets (15 grains) every eight hours orally, was begun.

On March 27th the anterior chamber was clear, and the corneal transparency had increased. The iris still appeared grayish and muddy.

On the following day the vision of the left eye had improved to perception of

hand movements before the eye. The conjunctival flap was reddish, and its margin did not appear purulent.

On March 29th the exudate had been almost entirely absorbed. The corneal transparency was markedly increased, and the structure of the iris was more distinct. The next day's examination disclosed a further clearing of the structure of the iris. The old cataract wound was free of infiltration. The tension of the eye was decreased.

On April 7th treatment with sulfamerazine was discontinued, and the patient was dismissed from the Hospital. The condition of the left eye was then as follows: Several horizontal ruptures were noted in Descemet's membrane. The aqueous was clear. The pupil was slit-like, with several synechiae. A secondary membrane of the fibrous type was present. The previous cataract wound was perfectly healed. Superficial and deep vessels could be seen in the upper portion of the cornea. The tension was normal to palpation. Vision sufficed to count fingers at 6 inches.

Summary and Conclusions. A case of suppurative endophthalmitis is reported in which penicillin was administered successively every three hours over three days, with resultant clearing of the condition. No harmful effect on the patient's general condition was observed during the administration of penicillin.

Sulfa drugs did not inhibit the development of the endophthalmitis, but proved to be a valuable complementary therapeutic agent in addition to the treatment with penicillin.

1801 Bush Street.

LUXATION OF LENS WITH VOLUNTARY CONTROL*

OTIS R. WOLFE, M.D.

Marshalltown, Iowa

AND LEO L. MAYER, M.D.

Saint Louis

Odd and curious pathologic conditions relieve the monotony of the more common eye diseases. Because of its uniqueness, we present an eye condition unlike any before recorded in the literature, as far as we have been able to discover.

Mr. M. C. B., aged 40 years, presented himself at the Wolfe Clinic on May 2, 1944, with the following history:

In 1919, while a member of the Armed Forces in World War I, stationed at Scofield Barracks, Honolulu, Hawaii, a box of dynamite caps exploded in his face. It was necessary to remove the left eye immediately in the Army Hospital. The right eye was blind and received treatment in the Hospital until January, 1920, when the patient was discharged, for vision was now good in the remaining eye. Previous to entering the Army the patient had been a boxer but had no known trauma to the eyes.

Upon his discharge from the Army the patient worked in a tire repair shop until 1927. While sparring with his brother he noted a sudden haziness of vision, although the eye had not been hit. He went to a physician in Des Moines, Iowa, whose name he does not remember. This physician gave him a lens which "made my vision better than it had been at any time after the dynamite explosion." In 1937 he began to see colored rings around all lights, had some dimness of vision, and noted a sticking sensation in the eye. He consulted another ophthalmologist but was not relieved. Two weeks later, because of this sticking sensation,

*From the Wolfe Clinic, Eye Department, Deaconess Hospital.

he sought further medical advice and the physician gave him typhoid shots. The vision returned to near normal, but the sticking sensation became more annoying. The patient felt very definitely that a piece of metal remained in the eye, usually to the temporal side and above, but at

Fig. 1 (Wolfe and Mayer). Lens in anterior chamber

times traveled across the direction of the upper lid to the inner canthus, to return to its usual position after a short time (1 to 2 hours).

Owing to this annoying sensation and the diminution of vision, he visited a state university eye clinic in 1940. He was told the tension of the eye was raised. An X-ray study of the eye was said to be negative. He was given some drops to take home and use, and was told it would help.

Our examination revealed a corneal dystrophy, with marked clouding of the cornea, more in the entire lower two thirds and more especially in the lower temporal quadrant. Vacuoles were found in the central corneal area, and in this region an area 2 mm. in diameter stained irregularly with fluorescein. There was an abundance of new blood vessels in the lower temporal portion of the sclera running into the cornea to within 2 mm. of its center. The anterior chamber appeared deep and the pupil was small (2.5 mm.) and did not enlarge under mydriasis. The

sticking sensation persisted and vision was reduced to the perception of hand motion at 2 feet.

Tuberculin tests were negative. An X-ray study of the eye showed a small foreign body localized in the temporal sclera just above midline while the patient was under our care. One day he called one of us suddenly, exclaiming, "my lens is out." Lying in the lower anterior chamber was a dirty white, sclerosed, lenslike substance approximately 2.5 mm. in diameter. On further questioning the patient stated that this phenomenon had been occurring from time to time since 1927. After some maneuvering he was able to bring this lens remnant (see figure 1) into the anterior chamber and on other occasions he was able to repeat this dislodgment at will. Figure 2 shows the lens absent from the anterior chamber; on examination it was demonstrated to be posterior to the pupil. A high plus lens did not enhance vision at either position, although the

Fig. 2 (Wolfe and Mayer). Lens absent from anterior chamber.

patient showed a +13.00D. sph. which had been given to him in 1927 but which had been of little use since 1939.

The maneuver by which he brought the lens into the anterior chamber consisted of bending directly forward and then slowly turning the head with the right side going down until a shadow made

itself apparent to him. To dislocate into the posterior chamber, the patient would lie down on the bed and raise his chin slowly upward. It was more difficult to bring the lens into the anterior chamber than to dislodge it posteriorly. Through the cloudy cornea no details of the fundus could be made out. The slitlamp beam did not penetrate into the vitreous.

Attempts have been made to get previous history and findings from places the patient had previously visited professionally. Only one answer was received, this from a state university eye clinic. At the bottom of our letter of inquiry the following was written in pencil:

OD—Dislocated lens
Secondary glaucoma
Iridocyclitis
Small foreign body in orbit
Bullous keratitis

Because of the marked corneal disturbance we are keeping the patient under observation and have not advised surgery.

REPORT OF AN EYE INJURED BY LIGHTNING

PATHOLOGIC CHANGES

LOUIS B. SHEPPARD, MAJOR
(MC), A.U.S.

On August 11, 1943, the patient, aged 18 years, white, was admitted to the Station Hospital at Seymour Johnson Field, North Carolina, in an unconscious state, 15 minutes after he had been struck by lightning. Examination revealed that the patient had sustained second-degree burns to the head, involving the right eye. The subsequent ophthalmologic changes were of extreme interest. Because of the scarcity of similar reports in the ophthalmologic literature, this case was deemed worthy of record.

The patient remained unconscious for

four hours following admission to the Hospital, suffering anorexia and nausea for a period of three days, with some impairment of the sensoria. The subsequent clinical course, including the healing of the second-degree burns and excepting the eye condition, proved uneventful.

Ophthalmologic findings. Twenty-four hours after the incidence of the patient's injury, examination of the right eye revealed a marked edema of the upper and lower lids, moderate chemosis of the conjunctiva, and complete external ophthalmoplegia. The pupils were moderately contracted and equal in size. The cornea showed a wedge-shaped, whitish-gray opacity, extending from the 8- to the 10-o'clock position, with the apex in the pupillary region. This area did not stain. Two days later, on slitlamp examination, cloudiness was noted in the posterior half of the cornea. Vision in the right eye was light perception only and there was poor projection to light in the superior and temporal fields. The media were clear at this time.

Examination of the fundus, through a dilated pupil, indicated the loss of retinal transparency due to an edema surrounding the optic nerve which was most pronounced on the nasal side (fig. 1). No hemorrhages nor exudates were seen, and the vessels appeared normal in caliber. The intraocular pressure was normal to palpation and remained so throughout the period of observation.

Course. On the fifth day of hospitalization, the lids, conjunctiva, and cornea were clear. No lens nor vitreous changes were noted. The fundus revealed an increase in the retinal edema of the nasal and inferior portions. Projection continued poor in the superior and temporal fields. The functioning of the ocular muscles was normal. Vision in the right eye was perception of fingers at five feet; in the left eye, 20/20-3. The visual fields

of the left eye were normal and remained so throughout the period of observation.

On the fourteenth day of hospitalization, vision of the right eye was 20/200. At this time the patient had become ambulatory.

On the twenty-ninth day of hospitalization, vision in the right eye was 20/200; in the left eye, 20/20. Reexamination of the fundus of the right eye revealed a

bed with pinhole glasses in place and sandbags to each side of his head. Forty-eight hours later, the detachment was in place and the retinal edema had diminished.

At this time a circular area of redness was noted about the macula. The patient continued abed. The vitreous band decreased in size and shifted slightly toward the inferior temporal quadrant.

Fig. 1 (Sheppard). The fundus 24 hours after injury, showing edema of the retina involving chiefly the nasal and inferior portions adjacent to the optic nerve.

Fig. 2 (Sheppard). The fundus on the twenty-ninth day of hospitalization, showing a posterior vitreous band with fibrils extending nasally, edema of the retina, a small area of detachment adjacent to the nasal side of the nerve, and two separate areas of choroiditis.

whitish band in the posterior vitreous running vertically for a distance of $1\frac{1}{2}$ disc diameters above the nerve to a distance of $2\frac{1}{2}$ disc diameters below the nerve. This band had several small fibrils extending nasally and, apparently, attached to the retina. There was an area of retinal detachment 2 to 3 diopters in elevation adjacent to the nasal side of the nerve. There were two small, irregular, yellowish-white patches of choroiditis in the area of retinal edema at the inferior portion of the fundus (fig. 2). The visual field remained unchanged.

The patient was promptly confined to

On the forty-fifth day of hospitalization, a second detachment was noted in the inferior portion of the retina with 6 to 8 diopters of elevation. The vitreous band had several small fibrils extending to the detachment. There was an increase in the clouding of the posterior vitreous. The nerve head continued to appear normal in color (fig. 3). For the first time, small irregularly shaped opacities were seen in the posterior cortical layers of the lens. Projection was definitely decreased in the superior fields with vision decreased to the perception of fingers at five feet. At this time it was deemed ad-

visible to transfer the patient to a general hospital for further observation and treatment.

The patient was admitted to Moore General Hospital on September 26, 1943. The subsequent course of his progress was reported by the medical staff of that Hospital as follows: His course was uneventful until October 26th, when the right eye became painful and red. The

detachment because of the associated inflammatory processes.

The patient was returned to the Station Hospital at Seymour Johnson Field on December 22, 1943, for rehabilitation. On examination of the right eye at that time, the following observations were made: Vision in the right eye was perception of fingers at two feet; in the left eye, 20/30+2. The right eye had 15 de-

Fig. 3 (Sheppard). The fundus on the forty-fifth day of hospitalization, showing the posterior vitreous band with fibrils extending to the detachment of the inferior retina.

Fig. 4 (Sheppard). The fundus on the 136th day of hospitalization, showing a huge detachment of the retina of the inferior fundus. Several strands of fibrous tissue (retinitis proliferans) are seen.

diagnosis of acute iridocyclitis was made. The aqueous was turbid, with many cells floating in the anterior chamber. The iris was boggy. Several posterior synechiae were noted and K. P. deposits were found on Descemet's membrane. The patient was given the usual local treatments with atropine and hot applications. Artificial-fever-cabinet therapy supplemented the foregoing. After two weeks of treatment, the inflammation gradually cleared.

In the search for foci of infection, a mild prostatitis was found and eliminated. No surgery was advised for the retinal

degrees of divergence. Light projection was absent in the superior quadrants. The patient could distinguish hand movements in the lower temporal quadrant and only strong light in the lower nasal quadrant. The fundus of the right eye could not be clearly discerned due to an increase in the posterior cortical opacities of the lens and the vitreous opacities. However, a complete detachment of the inferior retina was visible (fig. 4).

The patient was discharged to light duty on December 27, 1943, on the 136th day after the injury.

Comment. Haab,¹ in 1888, and Oliver,² in 1896, each reported a case of retinal changes following flashes of lightning which terminated in blindness. In the British Journal of Ophthalmology, 1929, J. N. Roy³ reviewed two such cases. The first, that of a girl aged 11 years, described a severe bilateral neuroretinitis following exposure to several flashes of lightning. Blindness resulted. The second case was that of a boy, aged 12 years, who was stunned by lightning and later showed ophthalmologic changes resulting in optic atrophy.

Two causative factors should be con-

sidered in evaluating the progressive organic changes observed in the present case. One of these factors may be photochemical action; the other, a thermal action or, more likely, a combination of both. The posterior-vitreous changes with the resultant band formation suggest that there was organization following coagulation of the posterior ocular structures. It is probable that the vitreous band was attached to the retina and its contraction may account for the detachment. Since there were areas of exudation, it is also probable that these may have been a factor in causing detachment.

THE SINISCAL-SMITH LID EVERTER*

ARTHUR A. SINISCAL, M.D.
Rolla, Missouri

A new type of instrument[†] for everting the upper eyelid is presented herewith. It is hoped that this will fill a long-desired need in the ophthalmologist's armamentarium by affording a quick and simple means by which the upper lid can be everted and the underlying conjunctiva widely exposed to view, displaying the retrotarsal fold and the whole upper cul-de-sac with a minimum of discomfort to the patient. The instrument is an outgrowth of the glove-buttoner which was

used in the Trachoma Clinic in Rolla, Missouri, many years ago and which was later reshaped by one of the co-designers[‡] into a more suitable form for everting the upper lid and examination of the cul-de-sac; from this, it was redesigned by the writer into the present model and presented to the ophthalmic profession for more general use. The instrument will supplant some of the older types of lid instruments used, most of which are primarily lid *retractors* and not suitable for routine use in the office or clinic as lid everters. Because of their bulk, or complex design, many of the older instruments used for lid everting become too unwieldy for everyday use, and, even when carefully manipulated, the lid integument occasionally became traumatized. For these reasons, and also because

*From the Missouri Trachoma Hospital. (Division of the Missouri State Board of Health).

†Manufactured by Storz Instrument Company, 4919 Forest Park Blvd., Saint Louis, Mo.

‡J. E. Smith, M.D., Huntsville, Alabama.

they were the source of general discomfort to the patient, many of them failed to gain popularity.

The lid everter illustrated here (fig. 1)

Fig. 1 (Siniscal). The Siniscal-Smith lid evertor.

does not injure any of the lid structures, even when marked pressure is applied. By moving the handle from side to side, once the instrument is in position, in order to slide the loop along the skin surface from inner to outer canthal angles, all of the upper extensions of the conjunctival fold can be exposed to view. Its employment facilitates not only the examination of the inner recesses of the conjunctiva—useful, for example, in doubtful diagnosis of the conjunctivitis—but also the search for foreign

bodies that may have become lodged beyond the tarsal border; it aids in routine examination; in the demonstration of anatomic relationships; and also in the

employment of surface applications of therapeutic agents. When used for this latter maneuver, the instrument can be held entirely in the left hand (*vide infra*), leaving the right hand free for holding applicators or therapeutic solids, as, for instance, in the application of carbon-dioxide snow to the follicles of vernal catarrh.

The instrument, having only one end for use, is simple in action and control. It is held by its handle (corrugated) in the vertical position, with the concave side of the loop facing forward (fig. 2). The *right* hand holds the instrument, with its loop placed against the skin of the lid, well behind the upper tarsal edge, and, while grasping the ciliary margin between the thumb and forefinger of the *left* hand, one directs the patient to look down. By pushing down on the instrument handle while at the same time lifting the lid margin, a wide exposure of the underlying conjunctival surface is obtained (figs. 2 and 3). The extent of surface exposure can be controlled by the amount of pressure and counterpressure exerted on the instrument and lid margin, respectively. Figure 3 illustrates the everted lid held in place by the instrument, which is now

Figs. 2, 3, 4 (Siniscal). Application and use of the evertor.

held entirely by the *left* hand, with the handle fixed between the middle and ring fingers; this leaves the right hand free to apply medications (fig. 4), or for instrumentation, demonstrations, and the like.

Occasionally, a foreign body becomes lodged or embedded in the upper fornix of the conjunctiva, and escapes notice, during the regular search for its presence by mere eversion of the upper lid with an applicator handle, pencil, or some blunt instrument. In the author's experience the following interesting case was observed: A child was brought in to the Clinic for a supposed active stage of trachoma in one eye, showing a moderately swollen upper lid with deeply injected conjunctiva generally and especially in the upper limbus region. Upon careful examination of the upper recesses of the cul-de-sac, there was found to have lodged therein a cockle-bur which had become so deeply embedded as to have eluded discovery during previous routine examinations. A similar experience occurred in the hands of a colleague, who found in his particular instance a small splinter of wood lodged in the upper cul-de-sac and so well encapsulated that it made discovery almost impossible until a wide exposure of the fornix was obtained by marked eversion of the lid.

Trachoma Hospital.

REFRACTION CLINIC*

DISCUSSION BY ALBERT E. SLOANE, M.D.†
Boston

A housewife, aged 36 years, entered the hospital with many varying asthenopic complaints, which did not include diplopia but indicated that her eyes were never comfortable. Seven years ago she was

operated on for alternating esotropia. One year ago, an alternating exotropia was noted, for which a tenotomy of the external rectus of the left eye was performed, following which she got a good cosmetic result. However, her symptoms persisted. She was working in a factory, operating a weaving machine that required precise fixations at several fixed distances. It was this kind of work that fatigued her most.

EXAMINATION

Vision was R.E. 20/30; with a +1.50D. sph. \approx -0.50D. cyl. ax. 180° it was 20/20. Vision L.E. was 20/70; with +1.50D. sph. \approx -0.50D. cyl. ax. 60° it was 20/40+. The Maddox rod test revealed a hyperphoria of 5^A for distance and near in the right eye, and in the left eye an exophoria of 4^A for distance, 12^A for near.

The afterimage test showed both normal and anomalous retinal correspondence.

The cover test showed an esophoria for near and distance.

Glasses were ordered incorporating a total of 3^A divided between the two eyes partially to correct the vertical hyperphoria. She reported later that relief was not obtained. Base in prisms were given on two occasions but afforded no relief. Subsequently glasses were prescribed without prisms and again without relief.

DISCUSSION

I believe that we may eliminate the compound hyperopic correction as being the source of her trouble on the basis that the glasses were correct. It is safe to accept that a patient subjected to at least six tests of her refraction has proper glasses. This brings us to the muscle-balance situation. Some questionable features are encountered at this point: 1). An operation for alternating esotropia

* From the House Officers' Teaching Clinic, Massachusetts Eye and Ear Infirmary.

† Director of Department of Refraction.

does not generally restore binocular vision since binocular vision is not the picture of a true alternating esotropia. This is further borne out by the fact that an exotropia developed postoperatively since there was no binocularity to fixate the eyes and maintain them in the normal integrated position. Again, if the binocular problem were the basis of her trouble we would expect periods of diplopia, since 5^A of vertical error cannot easily be fused. All this would tend to argue against a heterophoria as the cause of the trouble. One test serves to uncover the true nature of this patient's binocular status. It was noticed that the eyes were cosmetically straight but that the cover test showed an esotropic condition both for near and distance. In spite of this esotropia noted objectively, the patient consistently showed an exotropic condition with the Maddox rod. Thus the patient had a convergent strabismus by cover test and a divergent strabismus according to the Maddox rod. The explanation for this lies in the fact that this patient has a well-marked anomalous retinal correspondence which was well developed and present for a long time. In this situation it is almost as though there were a false macula in the deviating eye. When the operations were carried out to correct this primary esotropic condition they were, strictly speaking, inadequate to correct it all, since an esotropic condition still existed as demonstrated by the cover test. However, the same operations went too far, inasmuch as they produced an exotropia. This could only be possible where the projection did not correspond to the position of the eyes. This condition is known as paradoxical exotropia. It is not amenable to correction with prisms or exercise and is best treated by ignoring the muscle condition. The aim should be to obtain a beneficial cosmetic result. Eventually suppression will adequately eliminate the symptoms.

QUESTIONS

Q. Would you expect the symptoms to be relieved by occlusion of one eye and would this not be a good diagnostic test?

A. I would not be surprised if the binocular symptoms did disappear, but I do not believe it is necessarily a diagnostic test.

Q. Why does the patient have discomfort if no single binocular vision is present?

A. Because in most cases of strabismus the suppression area of the deviating eye does not include the peripheral field; the new position of the two eyes may produce discomfort by the new relationship acquired by the peripheral fields.

Q. What is the significance of anomalous retinal correspondence?

A. This indicates that corresponding anatomic retinal areas do not correspond functionally; that an anomalous functional integration has been set up according to the nonparallel position of the two eyes. In this way the person with strabismus has no diplopia and still a full binocular field of vision.

Q. How could you get a Maddox rod reading if no binocular vision were present?

A. Very often the two eyes alternate so rapidly that the person may project as though he saw both images simultaneously.

243 Charles Street.

CORNEAL FORCEPS: NEW TYPE

WALTER MOEHLE, M.D.

Brooklyn, New York

The popularity of corneal sections closed by means of suture in the technique of cataract extraction has introduced various designs of forceps for the purpose of adequately grasping the corneal lip. The construction must be such that the

instrument maintains the corneal lip firmly for the placement of the suture without traumatizing the tissue. The majority have the disadvantage of sharp intermeshing teeth where the pressure of the

eliminates these difficulties. Each tip has a single tooth, 1 millimeter long, 1 millimeter wide, and 0.5 millimeter high; they are angulated at 45 degrees, wedge-shaped, and have a semi-sharp edge. Of

Fig. 1 (Moehle). Corneal forceps: new type.

bite of each tooth of the tip is not directly opposite in its grasp. Teeth which accurately oppose each other obviate this.

I have obtained satisfactory results with a simply designed forceps* that

* Made by Wm. Langbein & Brothers, Brooklyn, New York,

most importance is the fact that the edges of the two teeth directly oppose each other, so that, when in use, the pressure on the corneal lip permits a firm vicelike grip but does not tear nor bruise the tissue.

15 Schermerhorn Street.

SOCIETY PROCEEDINGS

EDITED BY DR. DONALD J. LYLE

SEMI-ANNUAL MEETING OF THE DEPARTMENT OF OPHTHAL- MOLOGY, THE GEORGE WASH- INGTON UNIVERSITY SCHOOL OF MEDICINE

December 4, 1943

DR. WILLIAM THORNWALL DAVIS,
Executive Officer
Washington, D.C.

The semi-annual meeting of the Department of Ophthalmology of the George Washington University School of Medicine opened with the presentation of cases by the staff of the Department of Ophthalmology. A paper on "Military aspects of ophthalmology" by Col. Frederic H. Thorne (MC), U.S.A., followed, after which Dr. William Thornwall Davis presented a motion picture of the disturbances of the vertical ocular motility. The meeting was concluded with the case discussions.

MILITARY ASPECTS OF OPHTHALMOLOGY (Abstract)

COL. FREDERIC H. THORNE (MC), U.S.A., stated that except for correction of refractive errors the extent of ophthalmic practice in the Army equals about that which was estimated before the United States entered World War II. Battle casualties are not included. At one station through which 136,000 trainees passed during a 12-month period, 613 ocular operations were performed, 304 were hospitalized for ocular disorders, and 11,996 were refracted and spectacles issued.

Visual requirements for general military service are 20/200 bilateral, correcti-

ble to 20/40 or better. However, before a man can leave for overseas duty his vision must be corrected to 20/40 or better and he must have in his possession two pairs of spectacles. Gas-mask-type spectacles must also be issued when binocular vision is less than 20/70.

The forced-refraction program has been unsatisfactory because of: (1) a lack of available medical officers trained in refraction; (2) the difficulty in keeping spectacles on those required by regulations to wear them; and (3) the inability of the contracting optical firm to furnish the spectacles in sufficient time to prevent clogging of the flow of the personnel through the various training centers. Because of the lack of medical officers, the bulk of the refraction work has fallen on the shoulders of the enlisted optometrists, supervised by a medical officer.

It is believed that the forced issue of spectacles should apply only to those who have a visual acuity of less than 20/100 and to those who are undertaking specialized training of one type or another, and its successful pursuit depends largely upon visual acuity. Permission should also be given to issue spectacles to those who exhibit asthenopic symptoms, provided, in the opinion of the examiner, spectacles are necessary.

Overall supervision of ophthalmology in all branches of the Army by an officer familiar with present-day problems is recommended. This officer should be stationed in the Surgeon General's office and be made responsible, under the Surgeon General, for the assignment of personnel and the coordination of all ophthalmic activities.

Since the bulk of refractions falls upon the shoulders of enlisted optometrists,

these men should be given adequate recognition, and it is recommended that those qualified be given a rating of Warrant Officer, Junior Grade.

Discussion. It was asked, with respect to the men who report at the time of induction for examination, and on whom it is customary for the technicians to get the best possible vision no matter how hard they have to "squeeze," what the outcome is when these men get in the Army.

Colonel Thorne replied that it is difficult to answer that question. So many men get in with very poor vision even though their induction examinations showed that they had normal vision. That applies usually to squint cases. As is known, a squint can be alternating or intermittent, but if it is a one-eyed squint, the vision in one eye cannot be corrected, but on the induction papers the findings show that there is normal vision in each eye. He said he thought that "squeezing" vision is fair enough; that is, if there is adequate vision for ordinary purposes. The induction centers encounter the same trouble that examiners have everywhere to get the men to read the chart so that the maximum visual acuity is obtained. They refuse to make any effort and it is practically impossible to obtain it on the mass population who go through the induction centers. There are a great many men to examine and pressure is exerted on them to either pass or reject them. It is impossible, therefore, to examine these men with great care and still hurry them through.

During the time from September, 1942, to about February, 1943, men were sent to the station hospital to which I was attached by their induction boards; the halt, the lame, and the blind. They even sent in a man with a broken back in a plaster cast. In the last few months apparently they are not being so hurried

at induction centers, as the examinations are being more carefully made. When a man is sent in now whose record says he has 20/50 or 20/70 vision, it can usually be accepted as accurate.

It was then stated that the question asked was intended to refer to the myopic. The technician examines them and records the vision obtained by squeezing their lids.

Colonel Thorne said he thought that if they have 20/200 vision with squinting they should have less than 20/200 without squinting or squeezing. This could not be classified as useful vision and he would say that they should not be allowed to stay in the Army.

Colonel Thorne was then asked regarding the number of refractions done under a mydriatic.

He said the great majority are done under a cycloplegic but now when a man is examined who is easily corrected with $-0.50D.$ sph. or $-1.00D.$ sph., that completes the examination. But for all practical purposes it can be said that all are done under cycloplegia. Five-percent homatropine is the cycloplegic used. In all probability it is not necessary in all cases.

DISTURBANCE OF THE VERTICAL OCULAR MOTILITY

DR. WILLIAM THORNWALL DAVIS presented a motion picture to illustrate this subject. "By far the most frequent and important type of paralysis of a single vertical motor anomaly is trochlear-nerve palsy" (Bielschowsky). Most statistics give too small a number of trochlear pareses because they are not recognized. It occurs at least half as often as abducens pareses, which is the most frequent of all.

The most striking sign is habitual torticollis; that is, a tilting of the head to one shoulder. This occurs only when the

oblique muscles are involved, either the superior or the inferior oblique; it does not occur when the superior or inferior recti are paretic. It is the two symptoms, torticollis and upshoot of the eyes with the head tilted to one shoulder, that present the distinguishing differences.

The differential diagnoses (torticollis and the upshoot of one eye with the head tilted to one shoulder) were demonstrated in a motion picture in a case of right superior-oblique paresis. This showed the characteristic posture of the head, or torticollis, and also the upshoot of the right eye with the head tilted to the right shoulder, but no upshoot with the head tilted to the left shoulder. A case of left superior-rectus paresis was also shown, which showed no upshoot of either eye with the head-tilt test.

ANOMALY OF THE OPTIC DISC

DR. ERNEST SHEPPARD presented the following cases:

Case 1. This patient was a man, aged 42 years. The vision in the left eye was 20/200 with $-1.00D.$ sph. $\approx +2.75D.$ cyl. ax. 90° . The history of always having had poor vision of the left eye was confirmed by available records. When first examined in February, 1942, the disc was elevated 4 diopters and so pigmented on the nasal side that the margin was not visible. There was less dense pigmentation extending 1 disc diameter nasally. There was a small striate retinal hemorrhage adjacent to the upper nasal border. The temporal half of the disc showed slight pigmentation. There was a large temporal choroidal crescent and also a patch of choroidal atrophy at the upper temporal edge. The elevation extended almost to the macular area, as described by Klien (Arch. of Ophth., 1936, v. 16, p. 624, case 8). The right eye was normal. The exophthalmometer readings were 23 mm., each eye.

The tension was 22 mm. Hg (Schiötz), each eye. The physical examination was normal. Roentgenograms of the chest, skull, sella turcica, and the optic foramina were normal. He showed a slight reaction to old tuberculin 1:10,000. The blood Wassermann reaction was negative. The tentative diagnoses were: (1) developmental anomaly (as described by Mann in "Developmental abnormalities of the eye," Cambridge Univ. Press, 1937, pp. 127 and 133); (2) choroiditis juxta papillaris of Jensen, of undetermined etiology.

It was asked whether there was any suggestion of a retinal septum or congenital septum, or if there was some tearing of the retina which might be a retinal septum extending a short distance behind the disc. This condition is described by Ida Mann.

Dr. Sheppard replied that there was no septum so far as he could determine. The patient was examined both with the Friedenwald ophthalmoscope and with the Gullstrand binocular ophthalmoscope and there was no septum nor were there any prepapillary membranes such as are seen in proliferative retinitis.

Case 2. This patient was a five-year-old boy on whom a history of left convergent strabismus since birth was obtained. The visual acuity was 2/200, left eye, with $+5.50D.$ sph. $\approx +1.00D.$ cyl. ax. 90° . The disc was elevated 4 diopters and obscured by gray tissue. There was a large scleral ring surrounding the disc. There had been no evidence of inflammation and no change in the appearance in 18 months. With occlusion the visual acuity improved to 20/70+2. The visual fields, as nearly as could be determined, were normal. A tentative diagnosis of developmental anomaly was made.

The possibility of malignancy in each case was considered.

PEMPHIGUS OF THE CONJUNCTIVA

DR. E. LEONARD GOODMAN presented Mrs. E. B. P., a white woman, aged 59 years, who was first seen in September, 1936, at which time she complained of having had a "cold" in each eye for the previous two months. No previous history of ocular pathology was given. The patient suffered some discomfort but no actual ocular pain. There was no increase in tears, but some increase in mucous formation.

Examination showed the palpebral conjunctiva of both lower lids to be thickened and boggy red with a thick gelatinous, pseudo-membrane in some areas. No bullae were present. A diagnosis of chronic muco-purulent conjunctivitis was made and zinc and argyrol solutions were ordered.

The patient returned three months later with an aggravation of her symptoms and beginning evidences of scar tissue formation in the conjunctiva of the lids and retrotarsal folds. A working diagnosis of pemphigus of the conjunctiva was made. There were no lesions of the skin or other mucous membranes present.

Laboratory findings were as follows:

(1) conjunctival smear—few pus cells, few epithelial cells, and staphylococci; (2) urinalysis—negative; (3) Wassermann—negative; and (4) tuberculin reaction (intradermal)—negative. The patient's diet was lacking in green vegetables and milk.

Medication prescribed was: (1) series of ultraviolet (cold quartz) irradiations; (2) Fowler's solution internally; (3) cod-liver-oil concentrate; (4) calcium lactate; (5) liquid petrolatum and 1:8,000 mercuraphen locally; and (6) correction of diet.

The acute inflammatory symptoms soon abated but symblepharon formation in both lower cul-de-sacs, most marked

in the nasal corners, became rapidly more marked in the succeeding three months.

The patient was seen again after a period of six years. She stated that the redness of her eyes had disappeared during this period except occasionally, until one month ago when the right eye again became persistently inflamed. The lower cul-de-sac on the right side was now obliterated nasally and on the left showed heavy cicatricial bands. The cornea in each eye was, so far, unaffected. The patient did not complain of tearing.

It was asked whether any surgery to relieve the adhesions would be indicated now that the case was in a quiet stage.

Dr. Goodman said that this patient came to him as a last resort about three years ago with that same question and he did not recommend surgery. He did not think she had enough symptoms to warrant surgery and if very careful surgery were attempted, the benefits obtained would not justify it. Unless her symptoms become worse, or the cornea becomes involved, he said he would not advise surgery.

RETINAL DETACHMENT IN CHILDHOOD

DR. FRANK D. COSTENBADER demonstrated two cases of retinal detachment occurring in children under the age of 15 years. It was noted that the incidence of retinal detachment during the first two decades of life is less than 0.02 percent according to Stallard, Lindner, and Arruga.

Case 1. A white boy, aged nine years, showed upon examination a large bilateral bullous detachment of the entire inferior retina of the left eye, presumably following a blunt blow eight months previously. No hole was demonstrated. Two operations resulted in an incomplete reattachment, remaining detachment being limited to the peripheral inferior retina. The visual fields, greatly reduced

before operation, showed only a restriction of 10 degrees in the superior peripheral field after surgery. Almost complete activity had gradually been resumed without additional detachment. Central vision was 20/70 corrected. Possible causes of incomplete cure considered were: (1) retinal bands and (2) choroidal tumor, although transillumination of the sclera had been constantly good.

Case 2. A white girl, aged 12 years, had an extensive detachment of the entire inferior retina in the right eye without demonstrable cause other than myopia. Two operations resulted in a complete reattachment with almost complete restoration of the peripheral visual field, and the final corrected vision was 20/50+. The left eye showed a detachment of the inferior temporal and a portion of the inferior nasal retina 16 months after the retina of the right eye became detached. The left eye was not operated upon, but physical activity was restricted and atropine instilled. The retina restored itself over a period of 16 months, even though physical activity was resumed. Final examination of the left eye revealed corrected vision of 20/30, peripheral visual fields restricted 5 to 10 degrees superiorly, and no evidence of residual detachment. It is interesting to note that both eyes were myopic. No tears or disinsertions were ever demonstrated. No evidence of intraocular inflammation was present except fine strands in the vitreous. All tests for acute or chronic systemic infections were completely negative.

It was asked, with regard to the second case, what the indications were for surgery on the one eye and the contraindications for surgery on the other eye with the same condition.

Dr. Costenbader said that the reason for not operating on the second eye was the objections of the parents. They did

not wish to have the other eye operated upon. With no treatment except reduced activity reattachment took place.

BILATERAL AMBLYOPIA DUE TO INCOMPLETE OPTIC ATROPHY FOLLOWING CRUSHED CHEST

DR. RONALD A. COX presented the case of a Marine who gave a history of having sustained injury when a jeep accidentally overturned, crushing his chest and causing massive internal hemorrhages. The patient was unconscious for three days and upon awakening was bilaterally blind. The peripheral areas cleared gradually in both eyes but large central scotomata remained, and the patient was centrally blind (20 months after injury).

Conclusions. From careful study of the case and the literature, the conclusions are: (1) That massive loss of blood from the body may cause serious loss of sight; although the patient may recover, with complete recovery from the anemia, the blindness is permanent. (2) That the evidence afforded by the ophthalmoscope points to thrombosis of the central retinal artery as the usual cause of the blindness that occurs in posthemorrhagic anemia. (3) That the blindness is due to degeneration of the retinal ganglion cells, together with their long processes which make up the centripetal fibers of the optic nerve, and that the diminution in size of the vessels is a result of and not the cause of the blindness.

FOREIGN BODY IN CATARACTOUS LENS LOCATED BY VOGT X-RAY TECHNIQUE

DR. RICHARD W. WILKINSON said that Mr. J. D., an automobile mechanic, aged 34 years, on July 8, 1942, was tapping a piece of steel with a hammer and something flew into the right eye. He was seen on July 9th at which time the injury appeared as a small superficial

abrasion near the center of the cornea. No foreign body was found at the time of injury. Within three days there was complete healing and the patient was discharged.

Three weeks after the injury he was inducted into the Army, passing all visual tests. In December, 1942, five months following the injury he noticed that the vision in the right eye was blurred and upon reporting to the Army doctors a diagnosis of traumatic cataract was made. He was studied at Fort Wayne and later at Atlantic City where several sets of X rays were taken in the usual way. However, no foreign body was found. There was no "pull" felt when the magnet was applied.

The patient was seen again in April, 1943, at which time there was a fully developed cataract in the right eye. Light projection was good. The pupils were equal, and reaction to light normal. Examination of the cornea showed a thinly veiled scar above the center which appeared, with the slitlamp, to be a penetrating wound. There was no evidence of injury to the iris. No definite tear could be made out in the lens capsule. The left eye was normal, vision 20/15.

The patient was referred to a local roentgenologist and again the report was "examination of the right orbit fails to demonstrate evidence of an opaque foreign body."

As this was a compensation case and in view of the length of time that had elapsed since the injury and the diagnosis of traumatic cataract made, the patient was referred to Dr. Jonas Friedewald, who, in turn, referred him to Dr. Maurice Feldman for X rays. Using the Vogt technique, Dr. Feldman found a minute opaque foreign body located apparently near the posterior surface of the lens.

In the summer of 1943, the patient

was discharged from the Army, and in September an extracapsular cataract extraction was performed, and the piece of metal was recovered from the lens substance. The patient made an uneventful recovery and the corrected vision was 20/20.

This case demonstrates the value of the Vogt technique where other methods of localizing the foreign body fail. A "bone-free" film, usually a dental film, is placed nasally to the eyeball and pressed deeply into the orbit, and soft roentgen rays are directed from the temporal side. The anterior segment is nicely presented without interference by the orbital bones. The X ray will show particles of metal, glass, cement, or stone in the anterior segment of the eye which are frequently not seen by other methods.

X-ray films were demonstrated showing a foreign body.

PENICILLIN IN OPHTHALMOLOGY

DR. LUDWIG VON SALLMANN presented a paper on this subject. He said that studies on the toxicity of penicillin for the eye revealed that solutions or ointments containing 0.25-percent sodium penicillin (about 300 Oxford units per cubic centimeter) were well tolerated by rabbit and human eyes in various types of application. Solutions of higher concentrations damaged the epithelium of the rabbit cornea. Frequent and continued instillations, the application of salves, corneal bath, and iontophoresis were studied. The concentration of penicillin in the aqueous after local and systemic treatment was highest by far with the ioniza-

tion method, moderate with corneal bath, and small with intramuscular injection. Penicillin was usually not detected in the aqueous after frequent and prolonged use of salves and instillations. The addition of two wetting agents, aerosol 1B and penetrasol B, did not change these results. Nor did the wetting agents increase the permeability of the cornea beyond that obtained with local anesthesia.

The effect of local penicillin on intraocular infections with three types of pneumococcus (types III, VII, and X), two strains of mannitol-positive *Staphylococcus aureus*, and two strains of *Cl. welchii* was studied and compared with the result of iontophoretic introduction of sodium sulfadiazine combined with the systemic use of the sulfonamide compound. In most series of experiments the lens was injured during the inoculation of the dilution of the culture into the anterior chamber. Penicillin therapy was greatly superior to the combined sulfadiazine treatment in checking acute infections with pneumococci and staphylococci. Penicillin was also effective in the treatment of pneumococcic infections when the interval between the inoculation and treatment was extended to 12 and 13 hours. Dilutions of *Cl. welchii* cultures were injected directly into the lens. This infection was not influenced by any treatment when it began six hours after inoculation.

Dr. Von Sallmann further stated that a limited number of clinical observations at the Institute of Ophthalmology and experimental data obtained on acute intraocular infections with penicillin-sensitive organisms indicate that treatment should be started as early as possible and before the suppuration of the anterior segment of the eye has reached a peak.

Dr. Von Sallmann was asked whether or not penicillin could be used in the treatment of vitreous conditions, to which

he replied that no penicillin was found in the vitreous after local and systemic introduction of penicillin.

SURGICAL TREATMENT OF TUMORS OF THE LID MARGINS

DR. ALGERNON B. REESE read a paper on this subject and presented slides to demonstrate his technique.

Dr. Reese said that surgery is preferable to irradiation in the treatment of most cases of epithelioma of the lid margins. He described two techniques in which he found satisfaction. One is indicated when approximately one third or less of the length of the lid must be resected and the other when more than approximately one third of the length of the lid must be resected. The principle of both procedures is a sliding graft from the temple. Some advanced cases of epithelioma of the lid should be treated by irradiation and surgery. These operations were also useful in the treatment of nevus of the lid margin and for the repair of postirradiation defects of the lid margin, congenital coloboma, and traumatic coloboma.

Dr. Reese said that for the treatment of a papilloma, excision with cauterization of the base is adequate because the lesion does not spread beneath the skin surface. Hemangioma is a nonprogressive type of lesion, and usually repeated injections of 5-percent sodium morrhuate is sufficient. For precancerous melanosis irradiation is indicated and for cancerous melanosis usually exenteration.

Question: If you have done an operation and you feel irradiation should be used, how soon after operation would it be advisable to use the X ray to a fair extent?

Answer: Dr. Reese said he knew of no case in which he had used irradiation after operation. He saw no reason why it should be carried out immediately.

Question: What should be done with very small epitheliomas such as one sees in private practice?

Answer: Dr. Reese said he thought that if the lesion is an epithelioma it would require resection of one third the length of the lid, and the simpler procedure is indicated.

Question: Most hemangiomas we see are in young infants. Is any treatment necessary for these? If you do undertake

treatment do you do it right away or do you wait a certain length of time, and, if so, how long?

Answer: There is a general rule for hemangiomas and that is the earlier they are treated the more sensitive and responsive they are to treatment. Radiation or sclerosing solution is used. Therefore, Dr. Reese said he thought the sooner you get after them the better.

Dr. Reese concluded by stating that the point he wanted to emphasize is the fact that these cases should be handled by ophthalmologists and that surgery gives the best result; that he saw no reason why ophthalmologists cannot treat them more satisfactorily than any other group.

Subscriptions, applications for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Miss Emma S. Buss, 5428 Delmar Boulevard, Saint Louis 12, Missouri*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

ACCEPTABLE PRACTICES FOR DISPENSING GLASSES

One of the most controversial problems that has confronted ophthalmologists throughout the years and seems today no nearer solution than it did 50 years ago is how to have the prescription for glasses for their patients filled in a satisfactory and ethical manner. Even the most acceptable practice—namely, that of referring the patient to a dispensing and nonrebating optician—has drawbacks and when one realizes that such opticians are available to only a few ophthalmologists, the impossibility of considering referral to such as the only sound practice becomes patently absurd. Can one say that because there may happen to be a

dispensing optician available he must be employed by the ophthalmologist? Suppose he is distasteful to him in other ways, even if ethical!

The writer has searched in vain for specific statements of policies enacted by the House of Delegates of the American Medical Association in regard to these matters. The ruling cited below applies to rebating only. It is enlarged upon in a "Report of the Reference Committee on Amendments to Constitution and By-Laws" in 1942, p. 70, adopted by the House of Delegates, but this also fails to refer specifically to the problem that concerns the ophthalmologist.

In Chapter III, Article 1, Section 5, of the Principles of Medical Ethics of the

American Medical Association it is stated "It is unprofessional to accept rebates on prescriptions or appliances or perquisites from attendants who aid in the care of patients."

Resolutions adopted by the Section on Ophthalmology of the American Medical Association at the Chicago Session, in June 1924, but never presented to the House of Delegates and consequently never adopted by the House, were as follows:

RESOLVED, That it is the sense of the Section on Ophthalmology of the American Medical Association that we deprecate the selling of glasses by the ophthalmologist to his patients in communities where the services of reliable dispensing opticians are obtainable; and

RESOLVED, That the acceptance of commissions or considerations, either directly or indirectly, from opticians and optical houses from the sale of glasses is absolutely contrary to all our standards of medical ethics and is just as reprehensible as the splitting of fees.

It would seem that far fewer ophthalmologists merely give the patient the prescription for glasses and permit him to enter alone into negotiations with an optician, and themselves have nothing to do with the finances of the procurement of the glasses, than those who share in the financial transactions inherent in dispensing the glasses in some manner or other. If this supposition is correct, it means that most of the eye physicians so acting desire, or are forced, to participate in the financial transaction. The secrecy which they maintain in regard to the matter indicates at least a lack of approval of the practice.

It is understandable that in the numerous communities where there are no dispensing opticians the ophthalmologist must find some other agency to fill his

prescription. Criticism has seldom been directed toward ophthalmologists who have dispensed their own optical goods and charged the patient for the glasses plus the physician's overhead if no dispensing optician was available. However, there are many who do not wish to enter into this mechanical and commercial phase of ophthalmology and seek for some other solution.

There are others who hesitate to ask the dispensing optician to make the numerous changes in lenses sometimes necessary before the patient is comfortable, without extra charge to the patient, yet themselves have no reserve account against which to charge the loss and would welcome some means of avoiding this situation. If it is granted, as is surely true, that most dispensing opticians do actually finance any changes that the referring ophthalmologist directs if made within a short period, is this not essentially a tacit business arrangement with the optician which he accepts in order to encourage patronage?

The question that the profession must decide is whether it is ethical for the ophthalmologist to enter into a purely business relationship with the patient in addition to his professional relationship. In its simplest terms this involves the furnishing of glasses at a price to the patient which will at least cover costs, breakage, mistakes, bad accounts, and so forth. It must undoubtedly be granted that this business will usually be conducted for a profit and may not be reflected to the patient in reduced cost to him, though undoubtedly it often will be. If it happens that the ophthalmologist does not have the time, the desire, or the mechanical bent to fit frames, mount lenses, and perform the many other duties of an optician, may he ethically employ a technician to do this and he himself conduct the financial transactions with the wholesale optician and the

patient as regards the glasses?

It has also been proposed that the eye physician may employ an agent to dispense the lenses at a price specified by the doctor and to collect the fees and turn over to the ophthalmologist any profit accruing from the transaction after deducting the agent's commission, overhead, costs, and so forth, or to charge any loss to the physician's account. The catch is that if the ophthalmologist specifies a price that seems too low to the agency his business will be refused. By too low is meant a price that is materially below the usual retail price in the community or any charge very close to the wholesale price, because such a charge would tend to reduce the general retail price. Manufacturers of optical goods are primarily concerned with the wholesale price in the setting of which they have the important voice and they will concern themselves very little about anything that will not affect this. But if anyone attempts to reduce this, let him beware!

Do these practices constitute rebating? Certainly the first two could not be so classed. They may, however, be associated with hidden profits for the physician, though this is not necessarily true.

There should not be a law, nor even a rule of ethics, in a democratic country that has not the approval of a majority and it is dangerous to have one that is violated by the majority. Can it be doubted that the present ruling as now generally interpreted is in that class?

It has proved demoralizing to the profession to have in effect a ruling that is so unpopular that it is not enforced and is essentially unenforceable. A definition of what exactly constitutes the rebating referred to in the Principles of Medical Ethics is needed. Some means of dispensing lenses that are available or can be made available to every ophthalmologist should be officially sanctioned by the medical profession. Nothing but in-

creasing dissensions can come from the present uncertainty. Therefore, it behooves the leaders in ophthalmology to formulate regulations that will cover these cases.

Would it not be a sound idea for the Executive Committee of the Section on Ophthalmology of the American Medical Association to formulate a resolution defining exactly what practices in regard to dispensing of optical goods may be ethically entered into by the members of the Section? If the resolution is adopted by the section, it should then be presented to the House of Delegates for adoption and thereby become the current ruling for ophthalmologists in organized medicine. An interpretation sufficiently broad to cover the various needs in different communities and under diverse circumstances might well settle this continually distressing question.

The writer has no desire to see a coat of whitewash applied to black practices. But he does believe that to declare certain procedures unethical and let it go at that is not sufficient, but that the positive phase of the question should be considered and a definition of what is permitted be given.

The writer is not ingenuous enough to believe that anyone who has heretofore had a profit from the sale of glasses that has constituted an important part of his income is going to give it up for any ethical consideration whatever. But a definition of ethical practices might be useful to newcomers into the profession who desire to follow the precepts they have learned in their training. It would be very helpful in ultimately rooting out bad practices if every national society, and local too, would adopt these principles as requirements for membership and make a special point of the matter in regard to candidates for enrollment. The American Board of Ophthalmology for many years had all candidates sign

an agreement not to accept any form of rebate, but this was discontinued because it was not possible to follow up the matter. Now there is a statement on the attitude of the Board in the matter which the candidate must read. Continued stressing of ethics by the Board, even if they think a pledge undesirable, cannot fail to influence well-educated young ophthalmologists who are entering practice with high ideals and great respect for the opinion of the Board members. It is not thought that passing new directives would bring about Utopia. Nor is this a police measure. It would, however, substitute a guide for a prohibition.

Lawrence T. Post.

MEDICAL SPAIN IN MEXICO

The praise and reverence accorded to great men, although not commonly so analyzed, has in large part a utilitarian purpose and effect. Such may have been the original design of the founders of that ancestor worship which is so all-pervading a feature of Chinese life, although it must be admitted that an important role may have been played by primitive man's tendency to assume continuity of existence for that mysterious psychic unit which we call the soul.

Regard for the merits and achievements of human forebears has undoubtedly contributed much to the development of morality and ethics. Such influences are seen in family tradition and in the ideals and tendencies of politics and science. When we assemble, either in person or in the creation of literary monuments, to honor one who during life accomplished great things for our chosen profession, we gain by the stimulus to activity along similar lines.

The greatest scientific workers are conspicuous not merely for their individual labors but also as leaders, as centers of schools of thought, method, and

investigation. Examples of such radiating influence are Newton the physicist, Harvey the physiologist, Koch and Pasteur the bacteriologists, and Galileo the astronomer.

A man who, during his long and very active life, and also after his death, was to be counted among the greatest not only in research but in leadership was born in 1852 in an obscure village of Spain. That country, often thought of chiefly in connection with tragic facts in her history, has produced many men distinguished in the arts of peace. Ramon y Cajal lived to receive the greatest honors bestowed upon scientists, including the Nobel prize. In life, and after death, he was revered by an earnest group of scientific workers of his own and other countries.

The ghastly civil war in which Spain pointed the way to the present worldwide conflagration had, among other disastrous consequences, the effect of driving into exile a number of those Spanish intellectuals who had espoused the democratic cause. Men formerly conspicuous in Spanish medical education are now to be found in several of the former colonies of Spain in the Western Hemisphere. One of these, Professor M. Márquez, long known among ophthalmologists as the founder of the Archivos de Oftalmologia Hispano-Americanos, is now practicing in Mexico City. A pupil and profound admirer of Ramon y Cajal, our distinguished colleague illustrates the fact that civil warfare has frequently benefited humanity by forcing into exile workers and thinkers who enriched the land of their adoption.

In Mexico City, a couple of years or so ago, Professor Márquez joined with other Spanish physicians "who now enjoy the hospitality of the Mexican people" in founding "El Ateneo Ramon y Cajal," a medical organization to which, says Márquez, the name was given with

"the idea . . . of placing our association under the egis of the greatest man of our race who has existed in the realm of biology . . ." On October 17, 1942, the new Ateneo joined with a distinguished and much older Mexican medical organization, the "Academia Nacional de Ciencias Antonio Alzate," in celebrating the eighth anniversary of the death of the famous neuro-anatomist. The Ateneo also created a new medical journal, "Anales de Medicina del Ateneo Ramon y Cajal," an impressive publication, of which four issues have so far appeared. The energetic editor of this publication, as might be supposed, is Professor Márquez.

The first issue of the Anales was devoted to the addresses delivered at the anniversary celebration just referred to, including a paper by Márquez on "Cajal, investigator and teacher," one by Julio Bejarano on "Cajal, the citizen," one by Martinez Baez on "Cajal, the biologist," and one by Tomás G. Perrin entitled "The voice of Cajal." (The Madrid "Center for Historic Studies" some years ago undertook the phonographic recording of the voices of distinguished persons, and a recording of Cajal's voice was reproduced at the meeting in Mexico City.)

Cajal, we are reminded by Márquez, "discovered a microscopic new world: that of the fine structure of the nervous system, fundamental basis for the knowledge of its normal and pathologic functioning." Of the central nervous system, Cruveilhier (quoted by Márquez) had said in 1871: "Of all the organs there is none whose study more excites our curiosity and unfortunately there is none whose texture is surrounded by denser shadows." It was left for Golgi and especially for Cajal to lift the veil.

A famous Italian psychiatrist wrote of Cajal "Without exaggeration . . . it may be said that modern neurology owes

above all to Santiago Ramon y Cajal the enormous progress made in the past century." A German physician, writing on the occasion of Cajal's death in 1934, said: "To Ramon y Cajal has been granted a fate which only very exceptionally falls to the lot of a man of science: he wished to make the name of his country respected throughout the whole world. This aim he attained."

Because the optic nerve and retina, with the optic tracts and centers, are a part of the central nervous system, the work of Ramon y Cajal belongs as much to ophthalmology as to general neurology. The new Mexican medical publication established by Márquez and his colleagues is a fine monument to Spain's greatest medical scientist.

CORRESPONDENCE

RELATION OF ANISOMETROPIA TO ANISEIKONIA

Editor,
American Journal of Ophthalmology:

In the May, 1943 issue of the American Journal of Ophthalmology we published an article entitled "A study of the aniseikonia in a case of increasing unilateral index myopia."

In this article we reported the measurements obtained between the years 1936 and 1942 in a case of anisometropia due to increasing lenticular myopia in the right eye. A close association between the anisometropia and the measured and computed aniseikonia was shown. We have had, since then, a chance to recheck this patient—in March, 1943, and in November, 1944. We thought that it might be of interest to you and your readers to have a short report on these follow-up examinations. Both in 1943 and in 1944 the patient returned complaining of recurrence of his symptoms of reading difficulties and of decreasing

Fig. 1 (Burian and Ogle). Graph of the changes in the spherical and astigmatic refractive errors of a patient with increasing unilateral index myopia over a period of eight years.

vision in the right eye. Objectively an increased density of the right lenticular nucleus was found, without a marked increase in cortical opacities.

The spherical refractive error in the

Fig. 2 (Burian and Ogle). Graph of the aniseikonia of the same patient, showing the marked increase that accompanied the progress of the anisometropia. The solid lines are the calculated figures.

right eye had increased to $-4.00D$. in March, 1943, and to $-6.50D$. in November, 1944. The corrected visual acuity of the right eye on these dates was 20/40+3 and 20/60, respectively. The refraction of the left eye had remained essentially unchanged. The aniseikonia, when the patient was last measured, had increased to 13.5% over-all in accordance with the increase in anisometropia.

The enclosed two graphs represent the changes in refraction over the entire period from 1936 to 1944, and the corresponding changes in aniseikonia for the same period of time.

CAPILLARY HEMANGIOMA OF THE PALPEBRAL CONJUNCTIVA

December 26, 1945

Editor,

American Journal of Ophthalmology:

In the November, 1944, issue of this Journal there appeared a pathologic report entitled "Capillary hemangioma of palpebral conjunctiva" by Capt. Otis D. Wolfe.

Several points in this case do not support such a diagnosis. Although the described tumor was covered with epithelium, microscopic examination revealed thin-walled capillaries, young fibrous tissue, and inflammatory cell—all typical of an inflammatory granuloma. The patient was noted to have had five chalazia previously. One of the most common causes of a polypoid mass of granulation tissue upon the palpebral conjunctiva is the rupture of a chalazion through the conjunctiva. The tumor described by Captain Wolfe suggests a similar origin. Reference—Duke-Elder, W. S. Textbook of ophthalmology. St. Louis, C. V. Mosby Co., v. 2, p. 1787.

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

1

GENERAL METHODS OF DIAGNOSIS

Crawford, H. E. Biomicroscopic surgery and treatment. *Arch. of Ophth.*, 1944, v. 32, Sept., pp. 215-216.

The author tells how he uses the biomicroscope in removal of foreign bodies of the cornea, treatment of ulcers, removal of sutures, and epilation of misplaced cilia. (2 references.)

R. W. Danielson.

Crisp, W. H. Pitfalls of the general physician in ocular diagnosis. *Rocky Mountain Med. Jour.*, 1944, v. 41, Sept., pp. 626-633. (See Section 18, Hygiene, sociology, education, and history.)

Disler, N. N. The unfrosted electric lamp in ocular practice. *Viestnik Oft.*, 1943, v. 22, pt. 4, p. 31.

Because of its greater intensity of illumination, Disler advocates the use of the unfrosted electric bulb for inspection of the eye, for oblique illumination, for indirect ophthalmoscopy, and for the hand slitlamp. An electric bulb with a filament of two or three coils is

more suitable than one with a longer filament. To provide a brightly illuminated area similar to that obtained with the slitlamp, a diaphragm with a slit over the bulb was designed by Disler in 1935. Such illumination is easily arranged where a slitlamp is not available, as for instance in field hospitals, and is helpful in the diagnosis of the varied ocular injuries seen at the front. With this illumination one can see the details of the iris, the lens, and the anterior portion of the vitreous body. The bulb may also be used for diaphanoscopy in outlining the presence of foreign bodies in cornea, iris, and lens.

Ray K. Daily.

Ellis, O. H. A new goniotomy lens. *Amer. Jour. Ophth.*, 1944, v. 27, Nov., pp. 1258-1265. (4 illustrations, fields, references.)

Feldman, J. B. An absolute monochromatic ophthalmoscope. *Arch. of Ophth.*, 1944, v. 32, Sept., pp. 213-214.

The author gives a description of an ophthalmoscope designed by himself. With this instrument it is imperative

that unfiltered light be never used; otherwise retinal damage will result. The instrument is of value not only as an ophthalmoscope, but also to illuminate the lens in surgery. Some surgeons use only ultraviolet rays after operations for cataract, to determine whether all the lens matter has been removed. The author, however, has found monochromatic yellow of greater value in illuminating the field after extraction of a cataract. The monochromatic ophthalmoscope is of value in questionable fundus cases, by making pathologic conditions stand out more prominently. (One illustration.)

R. W. Danielson.

2

THERAPEUTICS AND OPERATIONS

Adamiuk, V. E. Therapeutic transplantation of skin. *Viestnik Oft.*, 1943, v. 22, pt. 4, p. 12.

Adamiuk, to simplify the procedure introduced and popularized by Filatov, shortens the period of conservation of the transplanted skin from several days to several hours. For traumatic corneal opacities he transplants a small piece of skin under the upper outer part of the bulbar conjunctiva. Absorption of the implanted skin releases a number of biologic products which stimulate absorption of the corneal opacities. In cases in which the implant is absorbed rapidly a second implantation may be made. Whether the patient's own skin is just as effective as skin taken from another person and whether delayed absorption produced by rolling the transplant into a tube would be of advantage are problems to be solved in the future.

Ray K. Daily.

Bellows, J. G. Penicillin therapy in ocular infections. *Amer. Jour. Ophth.*,

1944, v. 27, Nov., pp. 1206-1218. (11 tables, references.)

Carreras, B. How to prevent hemorrhagic complications in orbital anesthesia. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1943, v. 3, Nov.-Dec., pp. 419-424.

The occurrence of orbital hemorrhage is very annoying although infrequent. To prevent these hemorrhages it is proposed that a sharp needle be used only for injecting novocaine beneath the skin. The deep injection is then made with a needle whose point has been blunted on a stone.

J. Wesley McKinney.

Cordes, F. C. Fever therapy in ophthalmology. *Jour. Amer. Med. Assoc.*, 1944, v. 124, Jan., pp. 14-23.

With a review of the literature, the author discusses the mechanism of the beneficial effect of foreign-protein therapy. He concludes that milk injections are of particular value in the treatment of infants; fever enhances the action of sulfonamides given concurrently. Although diphtheria antitoxin has many disadvantages, its use in sympathetic ophthalmia seems justified. Typhoid vaccine is the most widely useful agent, and small doses administered over a longer period of time seem as effective as larger, more shocking doses. Coley's mixed toxins are advisable when a milder fever is indicated or the use of typhoid vaccine is not warranted. Omnadin has some value in producing leucocytosis and a rise in the antibody content of the blood. The use of malaria is not justified for ophthalmic diseases. Hyperpyrexia induced by high-frequency methods is still in the experimental stage and further research is needed. Among physical means production of

fever is best obtained by air-conditioned cabinets of the Kettering type. It is most efficacious in gonorrheal and syphilitic diseases of the eye. (Discussion, bibliography.)

Robert N. Shaffer.

Crawford, T., and King, E. F. The value of penicillin in the treatment of superficial infections of the eyes and lid margins. *Brit. Jour. Ophth.*, 1944, v. 28, Aug., pp. 373-383.

Penicillin used locally as a solution (250 units of c.c.) or as an ointment (250 units per gm. of 30-percent lanette wax in water) was found to excel any therapeutic agent hitherto employed in the treatment of superficial infections of the conjunctiva, cornea, and lid margins. It also proved effective in stubborn cases which were resistant to other forms of treatment, sterile cultures being obtained within a few days after treatment was started. No case due to a penicillin-resistant organism was found. The four cases which showed recurrence after cessation of treatment were all due to organisms as sensitive to penicillin as those causing the original infection.

Penicillin proved just as effective in clearing up cases of conjunctivitis associated with skin lesions (seborrheic dermatitis, acne rosacea) as in uncomplicated cases. (6 tables, references.)

Edna M. Reynolds.

Knapp, F. N. Treatment of ocular tuberculosis. *Arch. of Ophth.*, 1944, v. 32, Sept., pp. 196-203.

After a review of the literature and reports of several cases, the author gives the following personal opinions as to the treatment of ocular tuberculosis: Rest in bed in a sanatorium or at home is urged. A high vitamin and high caloric diet is advisable. Radium

treatment is at times advisable, the beta rays for the cornea and the gamma rays for the more deep-seated lesions. Roentgen rays may also be utilized, although in general this therapy is only moderately effective and is usually limited to rather small and repeated doses. For chronic inflammatory lesions of the eye, the dose should be larger than for acute conditions, but it should never be so large as to endanger the structures of the most sensitive ocular parts, namely, the conjunctiva and the crystalline lens. Gold sodium thiosulfate is of value in some cases, although unfortunate local and general reactions have occurred. The author at times uses typhoid H antigen as advocated by Brown.

Mantoux diagnostic tests may be carried out by use of Seiber's purified protein derivative or old tuberculin. In the treatment of patients with ocular tuberculosis the aim is to cure by general treatment of the entire process in the organism, and not by treatment only of the local disease. Two main clinical groups of ocular tuberculosis stand in therapeutic opposition: on the one hand, malignant, exudative forms with the subjects toxin-sensitive, calling for conservative, general, and local treatment; on the other hand, benign, productive, or fibrous forms, with the subjects less toxin-sensitive, indicating a more aggressive therapy. (References, 2 illustrations, 1 in color.)

R. W. Danielson.

Mathewson, W. R. Vitamin P in ophthalmology. *Brit. Jour. Ophth.*, 1944, v. 28, July, pp. 336-346.

Two cases of ocular hemorrhage are reported in which vitamin P was used with satisfactory results. The first case was that of a patient with multiple myelomata accompanied by subarach-

noid hemorrhage, retinal venous thrombosis, and retinal hemorrhages. Nasal and bladder hemorrhages were also present. When vitamin P was given, the bladder and nasal hemorrhages ceased. No new retinal hemorrhages occurred, and those already present were absorbed. During temporary suspension of vitamin P, nasal hemorrhages recurred, but they ceased when administration of vitamin P was resumed. The patient had had X-ray therapy for the myelomata, so the question arises whether the increased capillary permeability was due to the disease itself or to the X-ray therapy. It is suggested that in myelomata and other conditions vitamin P may be used to lessen the danger of hemorrhage after X-ray treatment.

The second case reported was one of recurrent hemorrhages into the anterior chamber after cataract extraction. With the use of vitamin P the blood rapidly disappeared from the anterior chamber and the patient's general condition improved markedly. It is suggested that vitamin-P deficiency, as well as vitamin-C deficiency, may be a factor in the causation of cataract. (3 charts.) Edna M. Reynolds.

Moreu, Angel. A new model table for ocular operations. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1943, v. 3, Nov.-Dec., pp. 489-493.

The author's description is accompanied by photographs.

Oliveres, A. Preservation of zinc sulphate collyrium. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1943, v. 3, Nov.-Dec., pp. 449-451.

Preparations of zinc sulphate soon show a precipitation due to action of the air, of the alkaline glass, and of contamination by organic material. Ex-

periments were made with several preservatives and salicylic acid in 1 to 2000 strength was found to be the best. By adding this drug a clear stable solution was obtained, whose therapeutic effect remained unaltered indefinitely.

J. Wesley McKinney.

Riser, R. O. Modern trends in ocular therapeutics. *Arch. of Ophth.*, 1944, v. 32, July, pp. 70-75.

This material taken from recent literature gives an excellent list of powders, creams, pastes, refrigerating pastes, and ointments, intended for use on the eyelids. The therapeutic agents used systemically and locally in glaucoma are well classified and presented. A review of the indications for use of the sulfonamides includes reprinting of the excellent table presented by Thygeson. Under the heading of "better eye drops," Riser discusses tonicity, hydrogen-ion concentration, buffer solutions, preservatives, substitutes for tears, surface tension, and wetting agents.

A tabulation is given of the recommended hydrogen-ion concentrations in terms of the pH of various forms of buffered eye-drops. One may buffer one's own solutions, or one may specify Gifford's buffer solution or Feldman's buffer solution to the druggist. (References.)

Selfa, Enrique. The local use of the sulfonamides in some ocular affections. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1943, Nov.-Dec., v. 3, pp. 442-448.

Local application of the sulfonamides brings a high concentration to the tissues, and in external ocular affections it may be superior to use of the drug by mouth. Eight cases of acute conjunctivitis, three with pseudomembrane and

five without pseudomembrane, were observed. All responded rapidly to the use of sulfathiazole ointment locally. Of 12 cases of phlyctenular disease all but one responded well to sulfathiazole ointment. The response was much more rapid than that previously obtained with yellow oxide of mercury and calomel. Local application was very effective in inclusion blennorrhea and in gonorrheal ophthalmia of the newborn, and it is suggested that local application of sulfathiazole ointment might be more efficacious than silver nitrate in prophylaxis. In Koch-Weeks infection also sulfathiazole was effective, but in Morax-Axenfeld conjunctivitis no benefit was obtained.

Von Sallman, L. (with technical assistance of J. Di Grandi). Simultaneous local application of penicillin and sulfacetimide. *Arch. of Ophth.*, 1944, v. 32, Sept., pp. 190-192.

This paper deals with (1) preliminary experiments to determine compatibility of penicillin and sulfonamides in vitro, (2) iontophoretic application to rabbit eyes of a solution containing penicillin and a sulfonamide compound, and (3) the comparative effect of three types of therapy on a staphylococcic endophthalmitis produced in chinchilla rabbits.

It was found that sulfadiazine and sulfacetimide did not exert noticeable antagonistic effect on the bacteriostatic activity of penicillin in vitro. A single injection of 0.2 c.c. of a 10-percent solution of sodium sulfacetimide led to high concentration in the vitreous

and a lower in the aqueous, the level in the vitreous being close to 15 mg. per 100 c.c. 72 hours after injection.

Damage attributable to penicillin was limited in general to a slight inflammatory reaction without integral lesions of retina, lens, or vitreous. Repeated intravitreal injection occasionally caused permanent lesions of retina or lens. The irritation following injection of sulfacetimide was usually greater than following penicillin.

A reliable standard infection of the vitreous leading to phthisis bulbi was produced by intravitreal injection of 0.05 c.c. of a broth culture of *Staph. aureus* in a dilution of 10^{-4} . This infection was checked in all instances by penicillin if injected into the vitreous six or twelve hours after the inoculation; but the treatment was only of slight benefit when initiated 24 hours after inoculation. The infection was not influenced by intravitreal injection of sodium sulfacetimide six hours after the inoculation. (4 tables, 3 figures, references.)

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Enos, M. V. Suppression versus amblyopia. *Amer. Jour. Ophth.*, 1944, v. 27, Nov., pp. 1266-1271. (One table.)

Kekcheyev, K. Problem of night vision. *Amer. Review of Soviet Med.*, 1944, v. 1, April, p. 300. (See *Amer. Jour. Ophth.*, 1943, v. 26, Nov., p. 1236.)

Lancaster, W. B. Present status of eye exercises for improvement of visual function. *Arch. of Ophth.*, 1944, v. 32, Sept., pp. 167-172; also *Trans. Amer. Acad. Ophth. and Otolaryng.*, 1944, 48th mtg., p. 413.

Lancaster stresses the thesis that seeing is only one half ocular, the other half cerebral. There is abundant evidence for the general proposition that exercises, repetition, practice, and learning lead to better performance, to the acquisition of skill. Repetition and practice build up a substratum of memories useful for interpretation of sensations and facilitate the syntheses which are the major part of seeing. Motor functions are perfected by practice, and reflex pathways are facilitated. Ophthalmologists have concentrated their attention on the primary source of the sensation.

Lancaster is skeptical of actual structural changes being wrought by exercises, apart from the hyperplasia and hypertrophy of muscles and the consequent changes induced in tendons and perhaps in bones. Some clearing of corneal opacities often occurs, but not by means of exercises. It is doubtful that any changes in size or shape of the eyeball are brought about by such means. The burden of proof is on those who make such claims. (References.) R. W. Danielson.

McEachern, D., Layton, B. D. B., and Burr, E. G. Canadian Army night-vision training and testing unit. *War Med.*, 1944, v. 5, May, pp. 283-291.

The Canadian Army has developed a night-vision training and testing assembly, the operation of which is described. A preliminary group-training session uses landscape silhouettes projected at low brightness. The men are then tested individually. By the test

procedure men can be divided into four groups as regards night visual-acuity. The test-retest reliability appears to be satisfactory. The initial test will place a soldier in his proper category or on occasion in a category just below it. In no case has the initial test been shown to overrate the night visual acuity. Some units are mobile and equipped with portable dark room. Specially prepared silhouettes are used for the training of men on specific schemes or objectives. This form of training bears the same relationship to night field schemes as the sand table does to daytime maneuvers. (4 figures, 3 tables.) M. Lombardo.

Mayer, L. L. Effect of diethylstilbesterol on accommodation. *Arch. of Ophth.*, 1944, v. 32, Aug., pp. 133-134.

The author has noted a number of women with weakened accommodation, apparently the result of the administration of diethylstilbesterol. Five illustrative cases are reported. In most instances the androgen was administered for the relief of menopausal symptoms in patients presenting some degree of presbyopia. In these patients, a stronger reading addition was required than normal for their age. One of the patients was a 16-year-old girl whose near point had receded to 38 cm. In her, as in some of the older women, accommodative power returned to normal after administration of the drug was stopped. The use of diethylstilbesterol is known to be attended by some undesirable reactions, including, in order of frequency, nausea, vomiting, headache, vertigo, abdominal distress, diarrhea, and dermatoses. This article presents the first record of any ocular complication from the use of the drug. (References.) John C. Long.

Pascal, J. I. Intrinsic variability of astigmatic errors. *Arch. of Ophth.*, 1944, v. 32, Aug., pp. 123-124.

The variable factor occurs in the astigmatic correction at the plane of the correcting lens. When properly corrected for distance, the astigmatic eye develops a new astigmatic error when accommodating for near. The amount of this astigmatism varies with the amount and kind of true astigmatism, with the position of the correcting lens, with the nearness of the object viewed, and according to whether the amount of accommodation used is related to the meridian of greatest power or the meridian of least power. The amount of this induced astigmatism is ordinarily slight but may amount to 0.5 D.

Variability in axis of astigmatism may be due to any or all of the following factors: (1) cyclophoria: when the axis is determined with one eye occluded, thereby producing dissociation, the finding will be off axis to the extent of the imbalance; (2) the compensatory rotation of the eye when the head is tilted toward either shoulder; (3) the binocular extorsion when the eyes change from distant to near vision. The extent of change in axis may possibly amount to 5 or 10 degrees.

In general, these variations in astigmatism do not cause any special distress except in hypersensitive eyes. Should the determination of axis be somewhat variable when tested at 20 feet, it would be better to select the more temporal position for the correction, in line with the physiologic extorsion. As near vision is generally more important, one might obtain a correction compromise by determining the astigmatic correction at some intermediate point, such as 40 or 50 cm. It should be possible to avoid the error

induced by cyclophoria, by locating the astigmatic axis during binocular fixation. John C. Long.

Pérez Llorca, J., and Jiménez Almenara, J. Changes in the index of refraction of the ocular media in animals given sulfonamides. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1943, v. 3, Nov.-Dec., pp. 425-431.

To determine whether a change in index of refraction might be the cause of the reported cases of myopia occurring in the course of sulfonamide therapy, the authors carried out several experiments on ox eyes in vitro. Increasing amounts of albucid and neopental were injected into the anterior chamber. No appreciable increase in index of refraction was noted. The cornea, lens, and vitreous were submerged in various concentrations of the same drugs for 24 hours, but again no appreciable increase in the index of refraction was noted.

J. Wesley McKinney.

Prado Durval. Let us rationalize our optometric scales. *Arquivos Brasileiros de Oft.*, 1944, v. 7, June, pp. 89-94.

The author is impressed by certain inconveniences in the use of letters for these scales, such inconveniences being related especially to the variable recognizability of the letters, to the facility with which they are memorized, and to the impossibility of their use with illiterates. The relative merits of the Landolt broken circle, the illiterate "E" of Snellen, and the open square of de Wecker are discussed. Prado also argues in favor of a test card graduated in 15 steps from 0.1 to 2.00 (0.1, 0.15, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1, 1.25, 1.50, 1.75, 2), because a number of individuals have acuity a good deal above Snellen's so-called normal or unity.

The Snellen illiterate "E" is particularly favored, and a new scale has been printed by a firm in the author's home town, São Paulo, Brazil. (2 figures, references.)

Sergievsy, L. I. Shortening the period of atropine cycloplegia by means of weak solutions of eserine. *Viestnik Oft.*, 1943, v. 22, pt. 3, p. 35.

With the above objective 0.25 percent eserine was used on 76 patients, and 0.5 percent on 27, the age of the patients varying from six to forty years. These patients had received instillations of 1 percent atropine for ten days, for refraction. During the first day the instillations of eserine were made five or six times; during the following days, as needed; the need being determined by inability to accommodate, and not by the size of the pupil.

The data show that it is possible to restore the function of the internal ocular musculature of the normal uninflamed atropinized eye in one day by instillations of weak solutions of eserine. In some cases final abolition of cycloplegia may be delayed six or seven days. The criterion of restored function was ability to read for eight hours, or the working day. Patients able to read for eight hours are considered able to work, even if at the end of the eight hours the action of eserine ceases. The effect of eserine on the atropinized ocular musculature increases with the number of instillations, setting in more rapidly and holding longer. It is suggested that in first-aid stations of industries and schools the failing effect of eserine may be restored by a single instillation. Ability to read for eight hours was attained within three days by instillation of 0.25 percent eserine; thus after three days

use of this drug workers and children may be returned to industry and school, respectively, provided they are supplied with eserine for use as needed. The effect of eserine varies in different people, and in the same person it may affect the pupil and accommodation differently. There was no significant difference in the effect of 0.25 percent and 0.5 eserine on the cycloplegia, but the disagreeable sensations caused by eserine are more frequent with the use of the stronger solution.

OCULAR MOVEMENTS

Burian, H. M. Motility clinic. Concomitant convergent strabismus with overaction of the inferior oblique muscles and dissociated vertical divergence. *Amer. Jour. Ophth.*, 1944, v. 27, Nov., pp. 1284-1287. (3 figures.)

Crowe, M. P. Familial spastic paresis with strabismus. *Arch. Dis. in Childhood*, 1944, v. 19, March, p. 32.

The presence of different degrees of weakness of spasticity, and of adduction deformity of the lower limbs in the five children of a family is described. Signs of an upper-motor-neuron lesion are present in all five. This condition, first noticed in infancy and presumably present antenatally, resembles the clinical entity described as Little's disease, with, in addition, the presence of ocular manifestations.

The occurrence of the five cases in one family would seem to exclude an infective or traumatic etiology, and the origin probably is, as described by

Collier, "a primary neuronc degeneration due to factors which are at present entirely elusive." Different degrees of hypermetropia, accompanied by loss of vision, exist in each child, and strabismus is present in four. Visual acuity is about 6/12 in each case.

An obscure common deprivation process may exist. Since neither the parents nor the grandparents have similar defects, any genetic factor responsible would seem necessarily to be of the recessive rather than the dominant type. But the parents are not related. Theodore M. Shapira.

Da Luz, Barbosa. More concerning strabismus. *Rev. Brasileira de Oft.*, 1944, v. 3, Sept., pp. 13-22.

A brief review in somewhat general terms, with several quotations from the literature of strabismus, is accompanied by the statement that orthoptic training is valuable not merely in strabismus but in some cases of asthenopia without error of refraction but with poor binocular fusion. Faulkner, S. H., Scully, E., and Carter, E. E. Operations on one hundred cases of convergent concomitant squint. *Brit. Jour. Ophth.*, 1944, v. 28, Aug., pp. 403-407.

To show the degree of success which can be obtained by operation combined with orthoptic treatment, 100 consecutive cases among children from six to 14 years of age at the Salford Municipal Hospital are reported. Forty-five of the cases showed satisfactory binocular vision at the angle of squint.

The first operations carried out were:

advancement and recession 48, bilateral recession 32, bilateral advancement 6, single advancement 8, single recession 4, single recession and myectomy of inferior oblique 1, myectomy of inferior oblique 1.

In 92 of the cases the eyes were rendered approximately straight by operation and orthoptics. One patient considered to be a case of psychologic squint was unimproved by a second operation. The other seven relatively unsatisfactory cases would probably have responded to further operation.

Hughes, W. L. Recession of the trochlea for reducing the action of the superior oblique muscle. *Amer. Jour. Ophth.*, 1944, v. 27, Oct., pp. 1123-1131; also *Trans. Amer. Ophth. Soc.*, 1943, v. 41, p. 307. (10 figures, references.)

Krewson, W. E., 3. Comparison of the oblique extraocular muscles. *Arch. of Ophth.*, 1944, v. 32, Sept., pp. 204-207.

This article compares and contrasts the anatomy and physiology of the two oblique extraocular muscles. The superior oblique is the longest muscle in the orbit, the inferior oblique the shortest. The superior oblique has the longest tendon of all the extraocular muscles but no check ligament, while the inferior oblique muscle has no tendon but the longest check ligament. The superior oblique muscle has the most variable insertion, the line being usually on the vertical meridian, anterior to the vortex veins; the inferior oblique muscle has the most constant insertion, being located on the horizontal meridian and posterior to the vortex veins. The superior oblique muscle has a contralateral innervation, while the inferior oblique muscle has an ipsilateral

or a bilateral representation. The superior oblique muscle acts as a depressor, the inferior oblique as an elevator; their respective actions increasing as the eye turns inward and decreasing as the eye turns outward. The former acts as an intorter, the latter as an extorter; both torsional actions increasing as the eye is turned outward and decreasing as it is turned inward.

Both muscles are reputed to act as external rotators, the action increasing as the eye turns outward and decreasing as the eye turns inward. In the case of the inferior oblique, however, there may be some question whether it acts as an internal or an external rotator. The superior oblique is the second most frequently paralyzed muscle; the inferior oblique the least frequently involved, the lesion being then often accompanied by internal ophthalmoplegia. Vertical diplopia is greater with paralysis of the inferior oblique than with paralysis of the superior oblique. The false image pointing to paralysis of the superior oblique leans to the normal (opposite) side, and that related to the inferior oblique leans to the affected (same) side. (References.)

Shure, I. I. Strabismus in adults. *Arch. of Ophth.*, 1944, v. 32, Aug., pp. 113-119.

This is an analysis of results in 65 cases of strabismus in adult males, all of whom underwent operative procedures and received orthoptic treatment. Each case was refracted under cycloplegia, the amount of deviation measured, the near point of convergence determined, the degree of fusion measured, and the presence or absence of anomalous retinal correspondence noted. The surgical procedure consisted of recession of one muscle often combined with resection and advancement of the opposite muscle. No patient in the entire series was dismissed until a thorough attempt had been made to develop fusion. Each patient was given orthoptic training with the stereoscope on removal of the bandages, usually about 48 hours after operation. Treatment consisted of two sessions of 15 minutes each day for one week, after which the periods were increased to thirty minutes. Some degree of fusion was obtained in approximately 60 percent of the cases. Amblyopia, suppression, poor fixation, and anomalous retinal correspondence were found to constitute definite obstacles

in the treatment. Transient diplopia was present in 75 percent of the cases immediately after operation. In only one case was the diplopia persistently annoying. (4 figures, references.)

CONJUNCTIVA

Benedict, W. L., and Iverson, H. A. Chronic keratoconjunctivitis associated with *Nocardia*. *Arch. of Ophth.*, 1944, v. 32, Aug., pp. 89-92.

Nocardia, a subdivision of the genus *Actinomyces*, has rarely been reported as a cause of ocular disease. A few cases of infection due to *Streptothrix* (a synonym for *Actinomyces*) have been recorded. The authors report an extremely chronic ocular infection associated with *Nocardia* in a Saskatchewan woman 23 years old. The disease in the eyes began at the age of seven years. There were episodes of ocular pain, lacrimation, photophobia, dimness of vision, and injection of the conjunctiva lasting from one to several weeks.

Examination revealed visual acuity of 3/60 in the right eye and 6/10 in the left. A few cilia were directed inward, and a grayish-white discharge was present. The inner surfaces of the eyelids presented either large patches of bright red granulation tissue or patches of scar. Posterior symblepharon was present. The right cornea showed finely granular infiltration throughout, as well as gross and microscopic vascularization of all parts of the cornea. During the four years that

the patient has been under observation, the condition has remained nearly stationary. Treatment with sulfanilamide, potassium iodide, zinc sulphate, and metaphen, and local application of the sodium salt of penicillin, have all failed to show any noticeable effect.

Eight cultures made during the four years have all shown an organism that should be classified as one of the *Nocardias*. This organism grows readily on all of the common laboratory media. It is a Gram-positive pleomorphic rod, which produces a typical mycelium under some growth conditions. The cultural characteristics are described in considerable detail. Inoculation in the rabbit, guinea-pig and mouse failed to produce a disease process. Corneal and conjunctival injections in the rabbit caused no morbidity. (2 figures, references)

John C. Long.

Berens, Conrad. *Ophthalmia neonatorum*. *Amer. Jour. Obstet. and Gyn.*, 1944, v. 47, June, p. 855.

In the school year 1906 to 1907, 28.2 percent of the pupils admitted to schools and classes for the blind were blind because of *ophthalmia neonatorum*. In the school year 1941 to 1942 the percentage was 5.6. These figures emphasize the great importance of the use of silver nitrate in the prevention of *ophthalmia neonatorum* and the value of the campaign waged by the National Society for the Prevention of Blindness for use of this preventive measure. Recent studies seem to indicate that silver is still the best preventive.

While silver nitrate is readily soluble in water, its solutions may gradually become concentrated by evaporation. Silver acetate crystallizes out as soon as a concentration of 1.2 percent is reached. Thus the danger of using a too concentrated solution is entirely

precluded in the case of silver acetate.

For the sulfonamide-resistant group, penicillin seems to offer great hope. If neither sulfonamide nor penicillin proves effective, artificial-fever therapy should be considered.

Bland, J. O. W. Spontaneous folliculosis of the conjunctiva in grivet and vervet monkeys . . . and the susceptibility of the grivet to trachoma virus. *Jour. Path. and Bact.*, 1944, v. 56, April, p. 161.

In grivet and vervet monkeys folliculosis of the lids develops spontaneously and can be distinguished neither clinically nor histologically from trachoma, to which these animals are susceptible. This condition makes the grivets and vervets unsuitable for trachoma research. To infection with trachoma, grivets respond by production of follicles in the fornices of the upper lids. Inclusion bodies, however, are never found. That the follicles are trachomatous is proved by the fact that the virus remains virulent for man even after four passages, producing clinical trachoma and the presence of inclusion bodies in smears.

Galpine, J. F., and Campbell, D. R. Unilateral membranous conjunctivitis, with complete cast. *Brit. Jour. Ophth.*, 1944, v. 28, Aug., pp. 412-414.

The patient, a girl aged six years, was hospitalized for a moderate attack of scarlet fever. After being given 3,000 units of antistreptococcic serum intramuscularly, angina and rash disappeared and a routine nose and throat culture was reported negative. Ten days later an inflammatory condition of the left eye developed, with a great deal of discharge suggestive of gonococcal ophthalmia. The lids showed a membrane, and although a culture from the eye was negative for diphtheria and positive for hemolytic streptococcus, 8,000 units of antidiphtheric serum was given as a precautionary measure. The good eye was protected with a Buller's shield. The child developed a vaginal discharge. Smears showed a large number of pus cells with organisms resembling gonococci. On culture, only staphylococcus albus grew. A second culture from the eye showed the presence of streptococci only.

A week later the membrane was so extensive that it almost hid the cornea, which had become cloudy in the lower half. The membrane was like chamois

leather and extended from the limbus as a complete lining of the conjunctival sac. At no time was the pre-auricular gland enlarged. The cornea looked as though it could not possibly survive, and 60,000 units of antidiphtheric serum was given. Two weeks after the membrane was first seen, it began to separate from the margin of the lower lid. This continued slowly, and three weeks after separation began the membrane came away as a complete cast.

Later there was recurrence of the vulvovaginitis, smears from which showed organisms indistinguishable from gonococci. The latter organisms, however, were never obtained in cultures. At the end of her stay in the hospital the child developed a high fever which persisted for twenty days. Sulfonamides were given intensively by mouth, in addition to local treatment of the eye. Examination after an interval of three months showed vision of 6/24 in the left eye, with a large degree of irregular corneal astigmatism. There was a slight opacity in the lower half of the cornea, with extensive vascularization. Edna M. Reynolds.

Pokrovsky, A. I. Pure hyperplasia, inflammatory hyperplasia, and an evaluation of trachoma. *Viestnik Oft.*, 1943, v. 22, pt. 3, p. 39.

Pokrovsky takes the position that trachoma is an inflammatory hyperplastic process, and not a pure hyperplasia, basing his opinion on the pathologic picture, the clinical symptoms, and epidemiology. After study of a large pathologic material of pure hyperplasia, as exemplified by leukomas, and of inflammatory hyperplasia as exemplified by tuberculous lymphogranulomatosis, he concludes that morphologically the changes in trachoma belong to the inflammatory

type. One of the characteristics of lymphoid tissue is its response to irritation by a lively multiplication of cells, a property common to young tissue; the conjunctiva responds to irritation in the same manner. The inflammatory hyperplasia is most apparent in follicles, which represent very young tissue; in addition to this hyperplasia there are present in the follicles and adjacent tissue also other inflammatory phenomena. The low vitality and the rapid destruction of the lymphoid tissue in trachoma follicles correspond to the process in tuberculous lymphadenitis and inflammatory lymphogranulomatosis. Ray K. Daily.

Quiroga, M. I., and Mendía, J. A. Syphilitic chancre of the palpebral conjunctiva. *Rev. Oto-Neuro-Oft.*, 1944, v. 19, May-June, pp. 81-83.

This region is one of the rarest locations for syphilitic chancre, which occurs here in less than two percent of all extragenital chancres. The mode of infection may be direct, as in kissing, removing foreign bodies with the tongue, spitting, and accidentally in perverted sex relationship; or indirect from infected objects such as towels and linens. With the chancre there is usually a pre-auricular or submaxillary adenopathy. The case of typical syphilitic chancre of the right lower palpebral conjunctiva here recorded was associated with neighboring adenopathy. Both the chancre and the lymphatic involvement cleared under arsenic and bismuth.

CORNEA AND SCLERA

Aparisa, Tomas. Contribution to the treatment of leprous sclerokeratitis. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1943, v. 3, Nov.-Dec., pp. 461-463.

Ocular leprosy is most frequently localized in the cornea and sclera. For

some reason the conjunctiva is rarely involved. Unfortunately treatment often fails to prevent involvement of the entire anterior segment of the globe in a repulsive leprous change. The treatment used at the Fontilles Sanatorium consists in sodium salicylate by mouth, calcium and neosalvarsan intravenously, fever therapy, and atropine and chaulmoogra oil locally. In some cases the corneal lesion is thoroughly curetted and covered with a conjunctival flap.

J. Wesley McKinney.

Ayoub, J. E. M. Desiccation keratitis. *Brit. Jour. Ophth.*, 1944, v. 28, July, pp. 347-355.

Twenty-five cases of desiccation keratitis occurring among troops fighting in the desert during the summer of 1942 are reported. The symptoms include abrupt onset of itching and smarting, with profuse lacrimation, marked photophobia, and definite visual disturbance. The objective findings are constant—episcleral injection with superficial corneal changes and irregular astigmatism.

The uniocular cases responded well to treatment by bandaging, but the bilateral cases did equally well with instillation of castor or cod-liver oil. Full mydriasis relieved the discomfort and hastened healing. In all except one case the cornea was healed and clear and the visual acuity restored to normal within from five to seven days. The etiology is probably drying of the cornea in cases of great fatigue, where the blinking reflex is reduced in frequency. (5 figures, 1 chart of clinical details.)

Brown, A. L., and Nantz, F. A. Corneal healing: adhesive power of aqueous fibrin in the rabbit. *Amer. Jour. Ophth.*, 1944, v. 27, Nov., pp.

1220-1224. (One figure, 2 tables, references.)

Díaz-Dominguez, D., and Arqués, E. Biomicroscopy of the corneal epithelium in conjunctival affections. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1943, v. 3, Nov.-Dec., pp. 452-457.

The authors report seven cases of the epithelial keratitis of Fuchs, characterized by irritation, lacrimation, photophobia, and haziness of vision. With slight injection of the bulbar conjunctiva, there were in the cornea many fine subepithelial infiltrates, more numerous at the center. The condition involved both eyes and cleared up in a few days. The causative agent is considered to be a virus. A review of the literature shows that similar superficial punctate infiltrates are encountered in epidemic keratoconjunctivitis, and often in acute conjunctivitis.

J. Wesley McKinney.

Grüter, Wilhelm. Herpetic ocular diseases in the light of modern investigations of the virus. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1943, v. 3, Nov.-Dec., pp. 494-496.

Grüter's investigations have shown that herpetic lesions of various parts of the body are caused by the same virus as is found in many corneal lesions. Inclusion bodies indicating the presence of the virus have been demonstrated in the corneal corpuscles and epithelium, and within the neurilemma sheaths of the nerves, without involving the axis cylinders. The increased cellular metabolism produces gas which causes separations of the corneal lamellae, epithelial vesicles and bullae, folds in Descemet's membrane, and lesions of the endothelium. There is a migration of monocytes into the cornea. If necrosis ensues, lymphocytes

and polynuclear cells appear. Many of these herpetic lesions are reversible. Thirteen herpetic ocular lesions are listed, including small ulcers of the lid margins, and keratitis vesiculosa, bullosa, dendritica, geografica, stellata, filiformis, striata, disciformis, parenchymatosa diffusa, endothelialis herpetica, and epidemica, as well as recurrent erosion of the cornea and herpes iridis. The treatment recommended is application of iodine to the superficial lesions and short-wave therapy to the deep lesions, the latter being based on the thermolability of the herpes virus. J. Wesley McKinney.

Jacoby, M. W., and Dominguez, R. White rings of the cornea. *Arch. of Ophth.*, 1944, v. 32, Aug., pp. 97-100.

Only a small number of cases have been reported of the characteristic opacity of the cornea first described by Coats. Two theories have been advanced as to their causation. Ballantyne conjectures that the white rings result from degenerative changes, calcareous or otherwise, in drusen of Bowman's membrane. Kuan states the belief that the lesion is due primarily to a disease of the terminal branches of corneal nerves and that this hypothetical disease may lead to necrosis of Bowman's membrane. Kuan further speculates that the ring results from a secondary change—proteic precipitation, fatty degeneration, or mineral incrustation—in the periphery of the necrosed part of Bowman's membrane. Only three authors have reported the microscopic examination of the excised rings.

Jacoby and Dominguez have had the opportunity of examining a corneal white ring in an eye that was enucleated because of complications following cataract extraction. The cornea

was immediately excised and fixed in dehydrated alcohol, and was later embedded in paraffin and sectioned. The rings were found to be made up of clusters of globules, some in Bowman's membrane but some superficial and others deep to the membrane. No hyaline masses could be seen above Bowman's membrane either inside or outside the ring. In the ring proper, where the deposit was heaviest, no trace of Bowman's membrane could be found. Various chemical tests indicate that the deposits contain calcium phosphate but no iron. Other substances must be present, as the clusters do not disappear completely under the action of acids. The findings in this case lend no support to either the theory of Ballantyne or that of Kuan. (5 photomicrographs, references.)

Leopold, I. H., Holmes, L. F., and LaMotte, W. O., Jr. Local versus systemic penicillin therapy of rabbit corneal ulcer produced by Gram-negative rod. *Arch. of Ophth.*, 1944, v. 32, Sept., pp. 193-195.

Two methods of obtaining information concerning the routes of administration in experimental animals allow one to predict the results to be expected in human beings. Both methods are essential. The first is to determine the concentration reached in the cornea by the various means of administration; the second is to compare the effects of the two methods upon a standard lesion.

The experimental data of this work show that this Gram-negative organism, obtained by routine culture of material from the conjunctival cul-de-sac of rabbit eyes, is sensitive to penicillin in vitro. The experiments demonstrate that this organism can produce

a corneal lesion when injected intracorneally. Development of the lesion can be prevented by local use of penicillin but not by intramuscularly administered penicillin. Once the lesion is established, local penicillin therapy benefits its course but does not prevent the occurrence of considerable ocular damage. Intramuscularly administered penicillin does not appear to alter significantly the course of the lesion when therapy is started 24 hours after injection. The organism was sensitive to the drug in vitro and in vivo, as determined by the "well" method of Fleming and associates. (References, 1 photograph.)

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Ayberk, N. F. About the three-symp-tom-complex. *Göz Klinigi*, 1944, v. 1, no. 5, p. 197.

This is about a syndrome often called the Bechtsched syndrome. The

main factors of this syndrome are: hypopyon-iritis with tendency to relapses, aphthous disease in the mouth, and ulceration on the scrotum or in the vagina. All symptoms are caused by the same agent, which is supposed to be a virus. Inclusion bodies were found.

Joseph Igersheimer.

Crawford, Robert. A case of corpora nigra with anterior synechia. *Brit. Jour. Ophth.*, 1944, v. 28, Aug., pp. 410-412.

Both irises showed large flocculi, one being attached to the back of the cornea. This flocculus had the appearance of being slightly stretched, and showed a bifurcation near the corneal end, although the end itself, about 2 mms. in diameter, was single. There was no loose pigment in the anterior chamber. It is suggested that in this patient one of the flocculi had passed through the pupillary membrane about the fifth month (when the marginal sinus is well developed and the anterior chamber is still shallow) and so had become adherent to the cornea. A brief description of the development of corpora nigra is given. (One illustration, references.)

Kosena, E. G. The pathologic anatomy of traumatic iridocyclitis. *Viestnik Oft.*, 1943, v. 22, pt. 4, p. 33.

This is a study of transitional forms, from septic endophthalmitis to sympathetic ophthalmia. The material consisted of 700 eyes enucleated within a period of three years. In 20 of these there was clinically sympathetic ophthalmia. In the rest the enucleations were done to avoid sympathetic ophthalmia.

In 70 eyeballs the microscopic picture was that of sympathetic ophthalmia as described by Fuchs, or of a series of transitional stages between it

and Fuchs's septic endophthalmitis. Of the 20 eyeballs, enucleated because the second eye developed sympathetic ophthalmia, 15 presented the classical microscopic picture of that disorder. A group of 47 eyes showed transitional stages, consisting in some cases of tuberculoid granulomata, and in others of changes characteristic of infiltrating uveitis and choroiditis. The rest of the 70 eyes had less pronounced uveal changes. The characteristic feature was their chronicity, associated in some cases, or in some areas of the same eye, with a tuberculoid structure, and in others with a picture of lymphocytic nodules. In 8 percent of the traumatized eyes removed for fear of sympathetic ophthalmia the pathologic picture was very close to the picture described by Fuchs as found after the second eye has become involved. This indicates that the conception of sympathetic ophthalmia described by Fuchs should be extended to include transitional and abortive phases.

Kosina supports the position maintained by Rohr in 1910, that the histologic difference between sympathetic ophthalmia and fibrinoplastic inflammation is only one of degree. She also believes with Meller that the initial stage of sympathetic ophthalmia is characterized by transitional histologic forms. She suggests that further elucidation of the pathogenesis of sympathetic ophthalmia may be afforded through the study of traumatized eyes enucleated prior to the development of clinical symptoms, to prevent sympathetic ophthalmia. Ray K. Daily.

Spaeth, E. B., and De Long, P. Detachment of the choroid. *Arch. of Ophth.*, 1944, v. 32, Sept., pp. 217-238.

The clinical condition commonly spoken of as detachment of the choroid

is probably a more common manifestation of a pathologic process in the globe than is generally supposed. It occurs not only with surgical procedures perforating the eye but also as the result of severe accidental trauma to the eye. It may be either hemorrhagic or non-hemorrhagic, and it appears as a terminal phase in pathologic conditions of the uveal tract.

The authors believe that the underlying pathologic process in the choroid is the same regardless of whether the condition is serous or hemorrhagic or both, and that the immediate cause may be connected with (a) an intraocular surgical procedure; (b) traumatic perforation of the globe, of either the posterior or the anterior segment; (c) trauma to the globe without perforation; or (d) inflammatory changes, which may be acute but usually are chronic and of long standing.

After corneoscleral trephining detachment of the choroid is common. Actually, it seems to be most common after this operation.

Fuchs classified choroidal detachments as serous, hemorrhagic (due to traction by cyclitic membranes) and transudative (as in an acute inflammatory process). The authors give twelve excellent case reports illustrative of these various types, and discuss the pathology in detail. Several photomicrographs of enucleated eyes are included. (14 figures, references.)

R. W. Danielson.

Vischer, M. B., and Carr, C. The rate of entrance of radio sodium into the aqueous humor and cerebrospinal fluid. *Amer. Jour. Physiology*, 1944, v. 142, Aug. 1, pp. 27-31.

The writers state that the rate of entrance of sodium isotope ions into the aqueous humor and cerebrospinal

fluid is important in connection with the mechanism of formation and the fate of these fluids. They conducted experiments to determine the rate at which $Rd Na_{24}$ approaches equilibrium between plasma and the fluids. The movement of sodium from the blood into the aqueous and the cerebrospinal fluid was studied in dogs of 10 to 20 kg., after intravenous injection of suitable amounts of the radio isotope as sodium chloride in an isotonic solution. After injection the blood level of $Rd Na_{24}$ was determined on samples of arterial blood drawn from the femoral artery. The blood was rendered incoagulable by oxalate, and plasma was used for analysis. At various times after the injection the aqueous was withdrawn from each eye and the cerebrospinal fluid from the cisterna magna. The results, presented in tabular form, show an approach toward equality of $Rd Na_{24}$ concentrations in plasma and aqueous over an hour after injection in animals anesthetized with nembutal, while in animals on which local anesthesia was used this rate was lower. The entrance of $Rd Na_{24}$ into cerebrospinal fluid was much slower than into the aqueous. After lengthy discussion of the results obtained the writers admit that while the experiments reported in their paper add information concerning the problems of the mechanism of formation and absorption of the aqueous they do not permit a choice as to which is the more acceptable assumption. (References, 1 figure.)

GLAUCOMA AND OCULAR TENSION

Rodigina, A. M. Bilateral infantile glaucoma associated with bilateral hemangioma congenitale (nevus flam-

meus). Arch. of Ophth., 1944, v. 32, Sept., pp. 214-215.

The author's case resulted in complete blindness at the age of 11 years. (One reference, 2 figures.)

R. W. Danielson.

9

CRYSTALLINE LENS

Archangelsky, V. H. Prophylaxis in intraocular surgery. Viestnik Oft., 1943, v. 22, pt. 4, p. 14.

Archangelsky advocates the use of a large preliminary conjunctival flap and a keratome-scissors incision in cataract extraction, as prophylactic against intraocular infection. The large conjunctival flap complicates somewhat the opening of the anterior chamber, but this difficulty is compensated for by the ability to make the incision exactly at the limbus, by having the surgical field completely isolated from the conjunctival surface, by complete closure of the wound, by firm coaptation of the lips of the wound, by isolation of the anterior chamber from the conjunctival sac immediately after the operation, by formation of a thin cicatrix, and by a less astigmatic postoperative correction.

RETINA AND VITREOUS

Ayres, Francisco. Ophthalmoscopy in the hypertensions. Arquivos Brasileiros de Oft., 1944, v. 7, June, pp. 95-110.

The author quotes extensively from various writers on the subject. (Nine illustrations, references.)

W. H. Crisp.

Bedell, A. J. Ophthalmoscopic signs of terminal hypertension. New York

State Jour. of Med., 1944, v. 44, Aug. 1, p. 1675.

The author records 11 cases demonstrating ophthalmoscopic signs of terminal hypertension. The discussion is confined to only one phase of the immense problem of hypertension, namely what fundus signs suggest a serious outcome. Patients are separated into those who come early, when there is still time to give advice as to how to live; those who are seen when only by extremely good care can death be delayed even for a short period; and those who are already dying. The author points out that it is unwise to consider papilledema, or choked disc, as caused by hypertension until brain tumor has been excluded with exhaustive tests. The author's object is to show how fundus changes aid in arriving at an opinion as to the probable duration of life.

Theodore H. Shapira.

Gözcü, N. I. Retinal hemorrhages as complication of malaria. Göz Klinigi, 1944, v. 1, no. 5, p. 187.

Ocular complications are rare in malaria. They may be caused by the parasites themselves or may be a consequence of malarial anemia. The author reports two cases with retinal and preretinal hemorrhages. In the first case some of the hemorrhages showed whitish centers, in the second case there was a group of whitish spots around a preretinal hemorrhage. In this second case the general anemia was very marked and therefore the whole retina was very pale. Joseph Igersheimer.

12

VISUAL TRACTS AND CENTERS

Popov, M. Z. Pathogenesis of the fundus changes in complicated cranio-cerebral injuries. Viestnik Oft., 1943, v. 22, pt. 4, p. 19.

The fundus picture in infected wounds with large osteodural defects is different from that seen in noninfected wounds with insignificant osteodural damage. In the author's material, infected wounds of the brain associated with large osteodural defects showed rapidly a papillitis in the contralateral eye; while on the injured side there appeared only a slight blur of the temporal side of the disc, a filling of the excavation, and a slight constriction in the caliber of the veins. As the intracranial process progressed the contralateral papillitis increased. On the injured side there was a hyperemia of the optic nerve, with increased blurring of the temporal edges of the disc and obscuration of the venous and arterial contours. The blood column of the veins became dull in the lower half of the disc, giving the impression of a diminished blood supply in this region.

In cases in which necrosis of brain tissue opened the ventricles and cerebrospinal fluid drained away, swelling of the disc and haziness of its contours diminished, the excavation of the nerve became distinct, and hyperemia subsided, but the haziness of the vascular contours persisted. Microscopically, in a fatal case the perineural spaces of the optic nerves were found infiltrated with round cells.

The fundus picture in cases of small noninfected craniocerebral wounds with insignificant osteodural defects was that of choked disc, differentiating this picture from that seen in septic processes, in which the veins are narrowed. In some of the aseptic cases there was a profuse exudate on the disc in the form of dots and striae, and small hemorrhages around the disc. Endophlebitis appeared early, giving the veins a segmented appearance. The ocular symptoms became more pro-

nounced, with diminution of the cerebral pulse, increased dural tension, intense headache, and necrosis of the prolapsed brain.

The author explains the pathogenesis of the fundus picture as follows: The brain reacts to every trauma with edema and increased intracranial pressure. The edema decreases the elasticity of the brain and reduces the amplitude of its pulsations. This diminishes its aspirating action on the centripetal fluid surrounding the optic disc, and produces venous dilatation and stasis similar to choked disc. In large osteodural defects the intracranial pressure is diminished and the fundus changes are less pronounced. In septic processes there is, in addition, the destructive action of a toxic infective agent on the capillary membrane. It disturbs the normal exchange of fluid between the capillaries and the brain tissue, and albumin appears in the cerebrospinal fluid. Albumin also appears in the intercellular spaces of the brain, in the spaces of the optic nerve, and in the perivascular spaces; the dilatation of the perivascular spaces causes the venous constriction seen in the fundus.

The presence in some aseptic cases of exudates and hemorrhages on the surface of the disc is associated with the development of venous dilatation, slowing of the blood current, and increased permeability of the capillary endothelium.

13

EYEBALL AND ORBIT

Abdulaev, G. G. Enucleation of the shrunken eyeball. *Viestnik Oft.*, 1943, v. 22, pt. 4, p. 21.

After enucleating a series of shrunken and torn eyeballs, the author recom-

mends the following technique: preliminary pantopon or morphine injection; anesthesia through the skin, pushing the needle close to the orbital walls; and producing diffuse infiltration of the retro-ocular tissues; another injection through the scleral conjunctiva to anesthetize the anterior ocular segment. Lid elevators provide a more convenient field than a blepharostat. The conjunctiva is separated from the corneal remnant and the ocular muscles are separated from the eyeball, leaving all cicatricial tissue attached to the eyeball. The optic nerve is sectioned, the eyeball removed, and the conjunctival wound closed horizontally with a continuous silk suture. In primary enucleations the author uses no sutures, but in shrunken eyeballs the cicatricial edges of the conjunctiva unite better if sutured, and leave a better stump.

Ray K. Daily.

Brown, A. M. *Protheses for the eye and orbit*. Arch. of Ophth., 1944, v. 32, Sept., pp. 208-212.

Most commonly a prothesis is needed only after surgical exenteration of the entire orbital contents. In this process, two overcorrections are necessary. First, the entire orbit should be sculptured slightly higher on the face than its opposite; second, the conjunctiva should be slightly more visible in the prothesis than in the normal eye.

Negocoll was formerly used for making impressions, but was not entirely satisfactory since it had to be cooled to a desirable temperature and then used quickly within the critical period, the margin for error being rather narrow.

Modern compounds for negative impressions are greatly improved. They are supplied in the form of molding powders and require mixing with dis-

tilled water only. They are then spatulated to a smooth, air-free mixture, and the casting of the impression is done in the usual manner. These compounds require no special equipment and produce accurate, detailed impressions of eyes without bad aftereffects.

The author emphasizes that in sculpturing restorations the objective is not to create a beautifully modeled part which attracts attention and admiration but to fashion a restoration that will permit the patient to become inconspicuous. (6 photographs.)

R. W. Danielson.

Sverdlov, D. G. *Techniques of enucleation, and improvement of the cosmetic result*. Viestnik Oft., 1943, v. 22, pt. 4, p. 22.

The author urges the use of cadaver cartilage as implantation material in enucleations, and in plastic operations for improving an unsatisfactory stump. In injured eyes with torn conjunctiva it is important to introduce a prothesis at once or soon after the operation. Failure to do so produces distortion of the conjunctival sac by adhesions, which can be corrected only by further surgery.

14

EYELIDS AND LACRIMAL APPARATUS

Katznelson, A. B. *When should restorative lid surgery be done*. Viestnik Oft., 1943, v. 22, pt. 4, p. 3.

After twenty months of war surgery done both early and late, Katznelson is convinced that early is to be preferred to late plastic repair. The most favorable time is when the wound has just closed and is not yet completely covered with epithelium. Early plastic surgery eliminates excision of the cicatrix, and the bed of the transplant is

formed by a cellular highly vascularized granulation tissue, which insures nutrition and vascularization of the transplant. Katznelson uses free skin-transplants from the back of the ear and the mastoid. In firearm injuries of the face the wounds are frequently very extensive and deep, reaching to the bone and sinuses. Resection of cicatrices in such areas may expose the nasal cavities and sinuses, and leave a very unfavorable bed for the transplant. Experience has proved that the transplant does not shrink after early surgery. It appears to the contrary that transplantation has a favorable effect on immature cicatricial tissue, and stimulates its absorption.

Leoz Ortín, G. Abortive treatment of acute dacryocystitis. Arch. de la Soc. Oft. Hisp.-Amer., 1943, v. 3, Nov.-Dec., pp. 476-486.

Acute dacryocystitis may occur in three forms: (1) catarrhal inflammation of the mucosa of sac and duct; (2) pericystic phlegmon with or without eventual abscess formation; (3) combined inflammation of the mucosa and of the surrounding tissue. In the first type, the primary consideration is establishment of adequate drainage by introducing drops of cocaine and adrenaline into the sac, followed by massage and irrigation. After the sac is completely emptied a few drops of 2 or 3 percent silver nitrate are instilled. The treatment is carried out daily, and as the inflammation subsides cyanide of mercury or zinc sulphate replaces the silver nitrate. In a purely pericystic inflammation wherein fluid passes freely into the nose, the treatment is that of any phlegmon. If suppuration ensues, the abscess is incised without entering the sac. If the inflammation is

both intracystic and extracystic, incision carried into the sac is usually necessary. J. Wesley McKinney.

López Enriquez, M. Pseudo-dacryocystoblennorrhea. Arch. de la Soc. Oft. Hisp.-Amer., 1943, v. 3, Nov.-Dec., pp. 474-475.

In two cases a small sacular fistula opened into the lower canaliculus near the punctum. Pus exuded continuously from the lower punctum and lacrimation was an annoying feature. In each case careful excision of the fistula resulted in complete cure.

J. Wesley McKinney.

Prior Guillem, Antonio. Permeability of the lacrimal canaliculi. Arch. de la Soc. Oft. Hisp.-Amer., 1943, v. 3, Nov.-Dec., pp. 487-488.

In 31 cases of obstruction of one or both lacrimal canaliculi permanent permeability was obtained. A probe insulated except at the tip is passed to the region of the obstruction. A diathermy current of 80 to 100 milliamperes is applied to the probe, and the diathermy current creates an opening through the obstructing cicatrix into the sac. The operation is followed by daily probing for eight to ten days. Permeability was permanent in all cases.

J. Wesley McKinney.

Soria Escudero, M. Unusual prelacrimar congenital malformation. Arch. de la Soc. Oft. Hisp.-Amer., 1943, v. 3, Nov.-Dec., pp. 471-473.

A small sinus of 2-mm. depth over the right lacrimal sac had been present since birth. The sinus was extirpated and found to be lined by skin. No connection with the lacrimal sac could be demonstrated. The condition was evidently due to failure of fetal develop-

ment as to closure of this small segment of the nasolacrimal sulcus.

J. Wesley McKinney.

Tikhomirov, P. E. Achievement of 25 years in the treatment of diseases of the lacrimal sac. *Viestnik Oft.*, 1942, v. 21, pt. 6, p. 39.

The first work on dacryocystorhinotomy in Russia was done by Awerbach, who in 1924 reported on 250 operations. By 1942 the number performed at the Helmholtz Institute was 6,000. There it is being taught to a large number of ophthalmologists, and it is now widely used throughout the Soviet Union. This operation restores to active service soldiers disabled by dacryocystitis, and should be performed by all ophthalmic surgeons and in all teaching institutions in the rear and at the front. Much work has been done on the treatment of epiphora not caused by dacryocystitis. The author has demonstrated that epiphora is more frequently caused by disturbances in the lacrimal punctum and canaliculus than by diseases of the lower portion of the system. The author and Pokhisova have both developed operations for eversion of the lacrimal punctum. Ray K. Daily.

Williams, J. L. D., and Hill, B. G. A simplified external dacryocystorhinostomy. *Brit. Jour. Ophth.*, 1944, v. 28, Aug., pp. 407-410.

A brief account of a technique which was used in six cases of dacryocystitis with stenosis of the nasolacrimal duct. The aperture in the bony nasal wall is made so that it lies directly opposite the medial aspect of the sac fundus. The mucoperiosteum of the nose adjoining the opening is removed, and no attempt is made to form it into a flap. An incision is then made in the medial surface of the lacrimal sac. This flap is hinged posteriorly, and is turned back to lie over the posterior lip of the opening into the nose. A piece of rubber tubing is placed through the nasal opening, projecting into the lacrimal sac for about 3 mm. and anchored at the external naris. Postoperatively, syringing through the lower punctum is carried out once daily, and the rubber tubing is removed after seven days.

The value of pre-operative lipiodol X-ray examination is stressed, as well as correction of any obstruction due to deflection of the septum.

Edna M. Reynolds.

PAN-AMERICAN NOTES

MISCELLANEOUS

II Pan-American Congress of Ophthalmology. Preparations are being continued for the II Pan-American Congress of Ophthalmology, and it is hoped that the second meeting will be held in November, 1945, in Montevideo, Uruguay. This Congress takes pleasure in announcing the forthcoming visit of its president, Dr. Harry S. Gradle, who is planning a trip to various countries in Latin America. He will give lectures at the ophthalmologic centers in these countries.

International prize. The National Society for the Prevention of Blindness of New York offers a prize of \$500.00 for the most valuable original paper adding to the existing knowledge about the diagnosis of early glaucoma or the medical treatment of noncongestive glaucoma. This award will take the place of two separate prizes of \$250 each which had been announced some time ago.

Papers may be presented by any practicing ophthalmologist of the Western Hemisphere and may be written in English, French, German, Italian, Spanish, or Portuguese. Those written in any of the last four languages should be accompanied by a summary in English.

The award will be made by the Society with the guidance of an ophthalmologic committee composed of Drs. John N. Evans, Frank C. Keil, Daniel B. Kirby, Arnold Knapp, John M. McLean, R. Townley Paton, Algernon B. Reese, Bernard Samuels, Kaufman Schlivek, Mark J. Schoenberg, Manuel Uribe Troncoso, David H. Webster.

Brazil. The Minister of Education in Rio de Janeiro has appointed Dr. Silvio de Almeida Toledo to give a course in Trachoma in July of this year under the auspices of the National Department of Health. Trachoma is prevalent in Brazil. The State of São Paulo alone gave treatment in the year 1943 to 8,253 patients, distributed among the 54 units, dispensaries, and stations of the Health Department. At the same time it gave away more than a half million tablets of sulfanilamide. The number of eye operations made on these patients was 1,459. Folders and instructions to advise against the contamination of trachoma were distributed to 26,957 persons.

Guatemala. The Ophthalmological Clinic of the Casas del Niño was founded last year under the auspices of the Lions' Club of Guatemala. Dr. R. Pacheco-Luna is the Director. The babies are examined on entering, and periodically afterwards.

Perú. Eleven of the chief Peruvian institutions and seven of the best organizations of this nature in the United States have joined as sponsors of the Second Regional Institute in Administration and Organization of Hospitals which was held in Lima, Perú, December 3 to 16, 1944, organized by the Interamerican Association of Hospitals under the auspices of the Pan-American Sanitary Bureau.

The program was drawn up by a Consulting Committee presided over by His Excellency Señor Dr. Manuel Prado, President of Perú, and by an Executive Committee under the presidency of Dr. Constantino Carvallo, Minister of Public Health and Social Assistance.

The program for the Lima Institute included a series of conferences, practical lectures, and round-table discussions of the most modern equipment and latest techniques in hospital administration.

SOCIETIES

Argentina. III Argentine Congress of Ophthalmology was scheduled for the middle of the month of October, 1944. It was held at the city of Córdoba and lasted for three days.

The Sociedad de Oftalmología del Litoral has elected the following officers to serve during 1944-45: President, Prof. Dr. Carlos Weskamp; Vice-president, Dr. Luis A. Gallo; General secretary, Dr. Arturo Etchemendigaray; Treasurer, Dr. Rafael García Ocha; Members, Dr. Enrique V. Vertotto, Prof. Adj. Dr. Isaac Cotlier, Dr. Juan Maggi Zavalía, and Dr. Raúl Novick.

The "Ateneo de Extensión Oftalmológica" organized a lecture by Dr. Alberto Urrets Zavalía on June 28, 1944. The title of his paper was "Comments on ocular tuberculosis."

Brazil. The Ophthalmological Society of São Paulo, through its president, Prof. Moacyr E. Alvaro, organized a visit of São Paulo oculists to Bello Horizonte in the State of Minas Geraes. This visit took place July 11-13, 1944. On the 11th, a surgical session was held and Dr. Orville Conti performed two dacryocystorhinotomies and an operation for pterygium with Arruga's technique modified by the operator.

A scientific session was held and the following papers presented: Dr. Renato de Toledo, "Anesthesia in ophthalmic surgery"; Dr. Nicolino Rebello Machado, "The visual apparatus in cephalic traumas"; Dr. Orville Conti "Care in the cataract operation (during operation, pre-operative, and postoperative)"; Dr. Laborne Tavares, "Laurence-Moon-Biedl's syndrome"; Dr. Oswaldo Silveira, "Iridocyclitis and in-

fectured varicose ulcer," and Dr. Ennio Coscarelli, "Retrocorneal hyaline membranes." On the 12th, a round table discussion was held on the subject of "Difficult cases."

On the 13th another scientific session was held and the following papers were presented: Prof. Moacyr E. Alvaro and Dr. J. Mendonca de Barros, "File for glaucomatous patients"; Dr. Armando Gallo, "On the prevention of glaucoma"; Dr. Orville Conti, "Modification of Arruga's technique in the operation for pterygium"; Drs. Hilton Rocha and Amelio Bonfili, "Gonioscopy and infantile glaucoma"; Dr. Laborne Tavares, "Cutaneous palpebral horn"; Drs. Hilton Rocha and Santiago Freire, "A new cycloplegic (preliminary report)."

The oculists from São Paulo were also given the opportunity of seeing the new public buildings constructed by the Municipal Government and of inspecting the social work carried out by the authorities.

PERSONALS

Dr. Moacyr E. Alvaro, professor of ophthalmology of the Escola Paulista de Medicina, visited the United States in October, 1944, in order to attend the meeting of the American Academy of Ophthalmology and Otolaryngology in Chicago. During his stay in the States, Professor Alvaro was one of the speakers at the October 12th meeting of the Chicago Oph-

thalmological Society. His subject was "Clinical effects of local use of sulfonamides in the eyes," which will be published in this Journal.

Dr. Miguel Medrano, has been appointed professor of ophthalmology of the Faculty of Medical Sciences of the University of Guatemala.

Dr. R. Pacheco-Luna has been elected medical director of the Society for Protection of Children.

Dr. A. G. Arathoon, holder of a Pan-American Congress of Ophthalmology—Kellog Foundation Fellowship, has been appointed ophthalmologist to the Military Hospital.

We regret to announce the death of Dr. Gastão Torres, founding member of the Sociedade de Oftalmologia e Otorrinolaringologia of Rio Grande do Sul, Brazil.

Prof. Silvio Abreu Fialho, of Rio de Janeiro, was recently elected to the Brazilian National Academy of Medicine.

Dr. Eugenio P. Fortin, of Buenos Aires, went to São Paulo, Brazil, in July, 1944, to lecture at the Study Center and the Ophthalmological Society. His subject for the lecture at the latter was "The true capillaries of the retina with comments on the anatomy of the fibers of the macular region.

NEWS ITEMS

Edited by DR. DONALD J. LYLE
904 Carew Tower, Cincinnati 2

News items should reach the editor by the twelfth of the month

DEATHS

Dr. Fletcher G. Asbill, Ridge Spring, South Carolina, died November 5, 1944, aged 76 years.

Dr. Thomas D. Brown, Ogdensburg, New York, died October 6, 1944, aged 71 years.

Dr. Harry X. Cline, Marion, Illinois, died October 15, 1944, aged 66 years.

Dr. George S. Dixon, New York, New York, died October 9, 1944, aged 91 years.

Dr. Clark B. Hatch, Newark, Ohio, died October 20, 1944, aged 65 years.

Dr. Frederick Krauss, Elkins Park, Pennsylvania, died October 9, 1944, aged 73 years.

Dr. John W. Moore, Gloversville, New York, died October 6, 1944, aged 66 years.

Dr. Leonard G. Redding, Scranton, Pennsylvania, died October 5, 1944, aged 59 years.

Dr. Wayne L. Snyder, Brookville, Pennsyl-

vania, died September 23, 1944, aged 63 years.

Dr. Green B. Taylor, Cameron, Texas, died September 2, 1944, aged 69 years.

Dr. Hartwell Weaver, Dickson, Tennessee, died September 17, 1944, aged 59 years.

MISCELLANEOUS

According to a recent announcement, Emory University will sponsor an ophthalmologic Seminar, from April 19th to April 21st, honoring the memory of Dr. Abner Wellborn Calhoun, M.D., L.L.D., who was born April 16, 1845. He was the first professor of ophthalmology of Emory University and a pioneer in Southern ophthalmology. All those interested in ophthalmology are invited to attend as guests of Emory University.

The guest speakers on the program will be Dr. W. L. Benedict, Dr. John Dunnington, Dr.

Harry S. Gradle, Dr. Parker Heath, Dr. Walter I. Lillie, Col. Derrick Vail, and Dr. Frank Walsh.

The fifth semi-annual refresher course in laryngology, rhinology, and otology will be conducted by the University of Illinois, College of Medicine, at the College in Chicago, March 26th to 31st inclusive. As the registration is limited to 30, applications will be considered in the order in which they are received. The fee is \$50.00. When writing for application please give details concerning school and year of graduation, and past training and experience. Write to Dr. A. R. Hollender, chairman, Refresher Course Committee, Department of Otolaryngology, University of Illinois, College of Medicine, 1853 West Polk Street, Chicago 12, Illinois.

The Toledo Hospital Institute of Medical Research has been given a grant of \$6,500 a year for a two-year period by the Synder Ophthalmic Foundation for research on the physiology of the eye especially in relation to glaucoma. Because of the war, research will be delayed until a physiologist with specialized training in the eye is available.

The first Gifford Memorial Lecture was given at 7:30 p.m. on Monday, January 15, 1945, at the Continental Hotel (formerly the Medinah Club), 505 North Michigan Avenue, Chicago, Illinois. The speaker was Dr. Francis Heed Adler, of Philadelphia, who delivered a paper on "The pathologic physiology of convergent strabismus."

SOCIETIES

The Washington, D.C., Ophthalmological Society held its regular meeting on January 8, 1945, at the District of Columbia Medical Society Building. The guest speaker was Dr. Ralph I. Lloyd of Brooklyn who presented a paper on "Proptosis." A motion picture on "Extraction of magnetic and nonmagnetic foreign

bodies" was given by Dr. Arno E. Town. The following cases were presented: "Perivascularitis" by Dr. Sterling Bockoven; "Pulsating exophthalmos" by Dr. Ronald A. Cox; "A detachment of the retina" by Dr. Paul Levatin; "Unilateral trachoma—questionable" by Dr. Roy A. Stewart; and "Disciform degeneration of the macula" by Dr. Richard Wilkinson.

The 824th meeting of the Milwaukee Academy of Medicine was held jointly with the Milwaukee Oto-Ophthalmic Society on Tuesday, December 19, 1944.

At the December meeting of the Brooklyn Ophthalmological Society Dr. James W. White spoke on "Choice of the fixating eye" and Dr. Rudolf Aebli discussed "The relationship between ptosis and ocular-muscle anomalies."

PERSONALS

On December 14, 1944, at the New York Eye and Ear Infirmary, E. M. Burchell, D.Sc., was honored by that institution in recognition of the 50 years of service he has rendered it. Honorary membership in the American Academy of Ophthalmology and Otolaryngology was conferred by Dr. William L. Benedict. Since the event has been reported in various news magazines, the Journal will content itself with joining with the medical and scientific world in wishing Dr. Burchell joy of his well-deserved honors.

Dr. Henry Haden was the guest of the St. Louis Ophthalmic Society on the evening of January 26, 1945. After a dinner given by the Society in his honor, Dr. Haden presented a classical paper on the comparative development of the retina and the brain in human embryos up to 40 mm. The similarity in the structure of the two organs as they develop was beautifully illustrated. It is hoped that this paper can be presented to the readers of the Journal during the coming year.

*Pontocaine
Hydrochloride*

in

OPHTHALMOLOGY

and in

RHINOLARYNGOLOGY

*Surface Anesthetic
with Prolonged Effect*

Dependable anesthesia
of the mucous membranes

is readily obtained by the topical application of Pontocaine hydrochloride. This widely used agent acts quickly, penetrates deeply, and gives prolonged anesthesia. A variety of operative and nonoperative procedures on the eye, nose and throat may be successfully carried out with small quantities of relatively weak solutions.

HOW SUPPLIED: For surface anesthesia in ophthalmology: 0.5 per cent solution in bottles of ½ oz. and 2 oz.

For surface anesthesia in rhinolaryngology: 2 per cent solution in bottles of 1 oz. and 4 oz.

*Not
a Narcotic*

ARIBOFLAVINOSIS

IDA MANN

Oxford, England

Ariboflavinosis is rare in England and much confusion still exists concerning its ocular signs. A good deal of clarification is required before one can reconcile such discrepancies in the literature as those between Tisdall *et al.*, who found ocular signs of it in 197 of 198 R.A.F. personnel examined (99.5 percent), Gregory, who only found 31 cases in 1,059 patients (3 percent), Wellwood Ferguson, who found 17 among 250 outpatients (6.8 percent), and Scarborough, who found 70 among 204 patients (34.3 percent).

These discrepancies tend to sort themselves into two groups with a high and a low incidence, respectively, and would seem to depend on whether the observers were ophthalmologists (and therefore conversant with the appearance of the limbus under different conditions and with different kinds of corneal vascularization) or not. Bessey and Wolbach, who showed that the ocular signs of ariboflavinosis could be produced experi-

mentally in rats, pointed out that the earliest detectable sign is corneal vascularization. In spite of this, subsequent observers have extended this statement to include congestion or engorgement of the normal limbal loops as well as what is clearly shown in Bessey and Wolbach's illustrations to be the formation of new vessels on the cornea itself. As ably pointed out by Gregory in 1943, there is often no discrimination in the literature [for example, Sydenstricker *et al.* (1940), and Kruse *et al.* (1940)] between circumcorneal injection and ciliary congestion, and between a full limbus and an actual invasion of the cornea by new vessels. In Sydenstricker's paper reference is made to a "marked congestion and proliferation of the limbic plexus," but no evidence is given for real proliferation as against the filling up of preëxisting but empty vessels. The former is a condition of great rarity, the latter is extremely common under a host of ordinary conditions, as pointed

Fig. 3. a, b, c, are scrapings from the sixth day; d, was taken on the fifteenth day. a, shows elementary bodies only, whereas they are mixed with initial bodies in b and c. The first typical but relatively pale inclusion bodies were found on the fifteenth day (d). Elementary bodies at the borderline of microscopic visibility. Giemsa staining, $\times 1350$.

out by Gregory. Indeed, it may sometimes (from irritative causes quite unrelated to ariboflavinosis) assume striking and peculiar vascular patterns, such as the concentric collateral vessels described by Vail and Ascher (1943). These may come and go in the same individual as the irritation varies, but even when they are not easily visible the empty vessels can always be seen with a slit-lamp.

It would therefore seem unwise to include the full limbus among the signs of riboflavine deficiency, the earliest certain sign of which should be taken to be a budding out of new capillaries from the limbal loops at their apices, with extension on to the true cornea. This should be present in both eyes and around the whole corneal circumference, although it may vary in depth in the two eyes. Even then, the final certainty must be the emptying of the new loops after administration of riboflavine.

Undoubted cases of riboflavine deficiency have not often been described in detail, so that the following case, which was more severe than those described by Gregory and Wellwood Ferguson, may be of interest. I am indebted to Mr. A. C. Houlton, who first saw the patient and suggested the diagnosis, for the opportunity of following it up.

CASE REPORT

J. H., aged 49 years, a bricklayer, first attended the Oxford Eye Hospital on December 1, 1943, complaining of red and sore eyes, tenderness over the left eye, which was extremely painful, and a dull ache in the right eye, which was also red.

On examination, the patient was seen to be a tall, well-developed, intelligent man; he looked pale and unwell. His eyes

were screwed up, red, and slightly lacrimating. The skin at the corners of his mouth was dry and slightly scaly, but not cracked. There was ulceration of the lower gum. The patient was edentulous, wearing a denture. He also complained of slight facial neuralgia. His tongue was clean and red but showed no fissures.

On examining the eyes, visual acuity was found to be 6/6 right and 6/9, part, left. The right eye showed severe conjunctival injection, the main vessels being intensely engorged. The limbal plexus was full. There were no new *conjunctival* vessels. The cornea showed marginal vascularization and opacities in the substantia propria. The vascularization was distinctive. It was in the form of parallel, radially arranged loops springing from the apices of the loops of the limbal plexus and extending in three arcades beyond this, slightly more than half way to the pupil margin. The vessels were so engorged with blood that they appeared to stand out from the surface. They could not be confused with the vessels of an engorged limbus, as the loops were longer and obviously of new formation, extending over clear cornea. They were not like the fine vessels of a trachomatous pannus, nor the brushlike vessels of interstitial keratitis. They were mostly subepithelial, but in the region of the opacities had penetrated the substantia propria to about a sixth of its thickness. They extended all round the circumference of the cornea. The opacities were subepithelial, grayish, about the same depth, or slightly deeper than the vessels, and were curved concentrically with, but farther out than, the pupillary margin. They were coarse, whitish patches in which the corneal lamellae were disturbed and split apart. In the right eye there was one definite one from the 5- to the 8-o'clock position and other faint, doubtful ones.

FIG. 1 (MANN). THE RIGHT (A) AND LEFT (B) EYES AT THE BEGINNING OF TREATMENT.

FIG. 2 (MANN). AFTER 10 DAYS' TREATMENT. SLITLAMP APPEARANCES IN REGION OF OPACITIES SHOWN BELOW.

The fundus was normal and the center of the cornea clear.

In the left eye the condition was similar, but much worse. The patient stated that he had had a small corneal ulcer in this eye five years previously, and this may account for the greater severity, as the old scar may have broken down. In this eye there were two concentric rings of opacities, one outside, the other inside the pupillary margin. The rings were not complete, but were broken up into seven or eight separate, somewhat kidney-shaped opacities. One of these showed some loss of substance and could be described as an ulcer, the others were sub-epithelial. The center of the cornea was clear, and vision remarkably little interfered with, in view of the severity of the condition. The iris was normal in both eyes (see figure 1).

The patient's condition was diagnosed as a case of ariboflavinosis (B_2 deficiency) and he was sent to the Oxford Nutrition Survey for testing. The report showed:

Blood riboflavine—17 $\mu\text{g.}/100$ ml. plasma (low)
 Dark adaptation—6° 1.94 log. m $\mu\text{l.}$ (poor)
 Blood vitamin A—75 i.u./100 ml. plasma (normal)
 Blood carotene—99 i.u./100 ml. plasma (normal)

The poor dark adaptation with a normal blood vitamin-A and carotene content is interesting, in view of Pock-Steen's assertion that "twilight blindness" is an early sign.

The patient was then closely questioned about his habits and diet. He stated that he was engaged in building a hospital, that he lived in a camp with 600 men and had all his meals at a Y.M.C.A. canteen. He did not draw his rations. The nearest inns and shops were three miles away and he did not supplement the canteen food, which was roughly as follows:

7:30 a.m. Breakfast:
 porridge occasionally
 bread (often sour)
 practically no margarine
 no butter
 ham, spam, or bacon
 1 egg in six weeks
 10:30 a.m. Lunch:
 Tea and bread and cheese, or bread and jam
 sometimes margarine
 12:30 p.m. Dinner:
 once a week meat and two vegetables otherwise ham, spam, minced meat
 potatoes (boiled) and beans
 occasionally fish or sausages
 had carrots twice in six weeks, turnips and onions occasionally
 semolina pudding or pie (jam)
 apple pie once in six weeks
 4:00 p.m. Tea:
 tea with dried (skim) milk
 bread, cheese occasionally, otherwise jam
 6:30 p.m. Supper:
 "finished up whatever there had been for dinner"; pickles added, and sometimes ham

No fruit. Green vegetables once a week. Beer once a fortnight, by walking three miles. Tobacco plentiful. The food was cooked a long time before he got it.

The patient began work under these conditions on October 15th. He had previously lived in his own cottage, where he cultivated three quarters of an acre and ate home-grown vegetables. After a little while at the camp he noticed that he often felt very hungry, though the quantity of food was adequate. He did not think the cooking was good, or the food always fresh.

After being examined on December 1st, he was sent back to the camp, told to continue with the food, but to take 15 mg. of riboflavine a day. He returned to Hospital on December 8th, stating that he felt much better in himself, but his left eye was very painful. The visual acuity of the right eye had improved to 6/5 part, but the left was only 6/18, probably due to the corneal ulcer. The ocular condition was about the same, and he was admitted to the Hospital, given atropine

to the left eye, riboflavine, as before, and the ordinary hospital diet:

Breakfast:

Bacon and potatoes
or porridge and potatoe cakes
or scrambled egg
Tea with milk

Lunch:

Cocoa made with milk, and biscuits

Dinner:

Irish stew and vegetables
Milk pudding

or

Roast mutton and 2 vegetables (potatoes and greens or carrots, etc.)
Pastry

or

Fish and 2 vegetables
Chocolate pudding

or

Meat pasty and 2 vegetables
Apple fritters and milk pudding

Tea:

Bread and butter (and jam)
or sandwiches

Supper:

Fish pie
Blancmange

or

Soup; bean pie
Milk pudding

or

Macaroni cheese
Milk pudding

or

Liver and bacon
Milk pudding

Within four days the congestion of the new vessels in the right eye was reduced to half and the left was improving. On December 21st he was discharged, feeling quite well. The right eye looked normal to ordinary inspection, but with the slit-lamp all the vessels could still be seen, although most of them were empty, with an occasional spurt of corpuscles. The opacity was still visible, but was less. There were no subjective symptoms.

The left eye was still under atropine, and there was slight photophobia. It was still redder than the right. The vessels were emptying and the opacities clearing (fig. 2). The pain and tenderness had all disappeared. Visual acuity had improved

to 6/9. The ulcer in the mouth had healed, the skin of the angles of the mouth was normal, and the patient felt quite well.

The patient was finally seen on April 26th. He had left the camp and was living at home, having no treatment and feeling very well. Visual acuity in the right eye was 6/5 and in the left 6/6 with correction (right emmetropic, left $-2.50D.$ sph. $\cong -0.50D.$ cyl. ax. 90°).

The new vessels in the right eye were all completely emptied, but were just visible by retroillumination with the slit-lamp. The corneal opacity seen in figures 1 and 2 was still evident. It was narrower and showed a brown pigmentation similar to that of a Hudson's line. This was just subepithelial, and the anterior third of the substantia propria was seen to be involved in the opacity. The left eye also was quite clear, although the ring of opacities was still present. A few of the vessels still conveyed circulating blood. The majority were empty. The opacities in the cornea appeared more fluffy and less dense than previously. The epithelium was intact, and the anterior segment of the eye apart from the cornea quite normal.

There are many points of interest in this case. The new formation of corneal vessels round the whole circumference in both eyes in undoubted and very characteristic. The concentric arrangement of the opacities just beyond the tips of the new vessels has not been specially noted before. Sydenstricker gives no details and Wellwood Ferguson states that he has not seen opacities in any of his English cases. The fact that the old ulcer broke down in the left eye may account for the greater pain in this eye, the other opacities in both being subepithelial. The passage of the vessels more deeply into the substantia propria in the neighborhood

of the opacities has not been described before, neither has the slitlamp appearance of splitting of the corneal lamellae in the opacities, as far as is known. The rapid emptying of the vessels under riboflavine treatment can probably be considered diagnostic, in spite of the improved diet and one day of Multivite tablets while in Hospital. It will be seen that the condition when well marked is very characteristic. It could not easily be diagnosed as anything else, certainly not

as either rosacea keratitis or interstitial keratitis. The cure was quite dramatic, the eye which received no local treatment doing as well, or better, than that which had atropine.

SUMMARY

A case of ariboflavinosis is described, with details of new vessels and type of corneal opacity.

The Eye Hospital.

THE SPACE EIKONOMETER TEST FOR ANISEIKONIA*

ADELBERT AMES, JR.†

Hanover, New Hampshire

It is universally recognized that the position of objects in the field of view can be more accurately estimated by binocular vision than by unocular vision. In any activity wherein accurate knowledge of the position of objects in the field of view is important, it is recognized that excellent binocular vision is necessary.

Various tests and procedures have been devised to determine the degree of excellence of binocular stereoscopic vision. These have all taken the form of determinations of the accuracy with which an observer can judge the distances between closely juxtaposed test objects (the actual positions of which are known where actual objects are used, or their disparity where stereoscopic cards are used).

Such tests are based on the assumption that binocular vision provides a basis only for a more accurate judgment of the relative distance between objects; that is, of relative depth. These tests usually are restricted to the central or axial field of view. Recent investigations, however, have shown that this is too limited a concept of the spatial clues provided by binocular vision; that, in fact, binocular vision not only provides a basis for estimating the relative distance between axial objects, but also for accurately estimating the position of objects relative to the observer and relative to each other. This

more extended capacity might be called "binocular spatial localization."

While the aforementioned so-called "depth perception" tests disclose whether or not the two eyes are being used together in binocular stereoscopic vision and the accuracy of the relative "depth perception" with respect to two juxtaposed objects, they do not give any indication of the normalcy or abnormalcy of the observer's "spatial localization"; that is, whether or not the observer sees objects to be situated where they actually are. An observer can have very accurate relative "depth perception" for juxtaposed objects and yet localize objects incorrectly relative to himself and relative to each other.

The correctness of a subject's binocular spatial localization is determined by the nature and amount of the anomalous incongruity between the ocular images received from the two eyes. Normal binocular spatial localization is based on a normal incongruity of the ocular images due to the separation of the two eyes. Where the incongruity of the ocular images differs from the normal, anomalous spatial localization will result.

Early in the research in aniseikonia, it was recognized that differences in the size and shape of the ocular images from the two eyes have an important relationship with binocular (stereoscopic) spatial localization. Objects may appear to be at different relative distances from each other and from the observer than they actually are, their shapes and sizes may appear to be altered, surfaces may appear to be tilted or inclined in directions different from what they actually are. This spatial localization is a phenomenon of

*From the Research Division of the Dartmouth Eye Institute.

†The author wishes to express his indebtedness to Prof. K. N. Ogle for invaluable assistance in the development of the space eikonometer, and to Prof. R. J. Beitel, Jr., for the preparation and presentation of the material contained in this manuscript.

stereoscopic vision; it takes place over the entire binocular visual field and is not restricted to discrimination of differences in depth only in the central field of vision. The basic facts concerning the relationship between anomalous binocular spatial localization and the differences in size and shape of the ocular images were brought out first in the early studies on the horopter¹ and later on the "tilting boards"² and "leaf room."³ These experiments have shown that individuals with normal eyes are very sensitive to changes in the relative size and shape of the ocular images. They can discriminate changes in binocular localization resulting from the introduction of size differences of as little as 0.125 percent to 0.25 percent between the images in the two eyes. Both the apparent changes in localization and the accuracy of discrimination approach the theoretic maximal limits to be expected, the freer the field of view is from unocular clues to localization, such as perspective from rectilinear detail and from known forms. Where such clues are present, as in the average room, the spatial distortions may not even be apparent. It must not be concluded from this that the incongruity of the ocular images—that is, the aniseikonia—is in some way compensated for. Rather, the observer is relying predominantly upon the unocular clues here and is not responding to the binocular stereoscopic clues (disparities between the two ocular images) for localization.⁴

The immediate and significant conclusion to be drawn from such results is that one's ability to localize objects accurately—that is, to see things *where* they actually are—can be markedly impaired by aniseikonia. Since it is *where* we see things that primarily determines our motor innervations and muscular responses, both bodily and ocular, it at once becomes clear how

aniseikonia can make it impossible for us to function efficiently or successfully. It is reasonable to believe, for instance, that the symptoms reported by aniseikonic patients may be traced to the frustrations attending the conflicting activities resulting from false localization.

With this in mind it was decided to explore the possibilities for developing a test means whereby the nature and amount of aniseikonia could be determined from the way in which an observer might localize certain test elements in space. The problem in design was to obtain a test field or environment the elements of which could be used, alone or in combination, to differentiate and measure each of the various types of aniseikonia. In instruments for determining binocular spatial responses, it is necessary to eliminate all empirical or unocular clues which would tend to interfere with the "pure" *binocular* (stereoscopic) space perception; that is, the space perception derived solely from disparities of the images in the two eyes. The simplest possible nonconflicting types of contours are necessary, adequately screened from other objects and influences that might yield spatial clues. A satisfactory method was achieved with the development of the "space eikonometer."

It will be the purpose of this paper (1) to describe the space eikonometer, (2) to describe the various types of aniseikonia and their effect on localization of the test elements, and (3) to describe the technique for measuring the amount of aniseikonia by means of the space eikonometer test.

THE SPACE EIKONOMETER

The space eikonometer will be described in two parts: (a) the test elements of the target, and (b) the test lens unit before the observer's eyes. See figure 1.

THE TEST ELEMENTS OF THE TARGET

The essential test elements of the space eikonometer target are:

- (1) Four smooth vertical plumb lines or cords;
- (2) A cross (or X) consisting of two smooth cords at right angles to each other and at 45 degrees to the vertical lines;
- (3) A removable vertical plumb line which passes through the center of the cross.

For easy identification, the smooth

This smooth cord, which is colored white, can be raised or lowered from the side of the frame.

Two vertical plumbs are suspended both in front of and behind the cross at distances of 24 inches. These cords are separated 19 inches, equidistant from the objective, median plane of the observer and also at right angles to that plane. The visual angle subtended by these cords is approximately 11 degrees. The smooth cords in front are colored green; those behind, white.

Fig. 1 (Ames). Schematic drawing of space eikonometer.

cords of the various test elements are colored differently.

The cross, stretched within a frame 5 feet square, is set up at a distance of 10 feet from a headrest for the observer. The center of the cross is at the height of the observer's eyes (49 inches—average height of eyes of seated person) above the floor. The plane of the cross is carefully mounted at right angles to the floor and to the objective median plane of the observer. The cords of the cross are colored red. A hole is bored in the top of the frame so that a cord with a plumb bob that passes through the center of the cross can be lowered, when desired.

In order that the test elements shall be as free as possible from empirical clues, the cords used are quite small. Theoretically, the thinner they are, the better. Further, the illumination of the test elements must be bright and uniform, without shadow.

For a background, a black cloth is stretched over a frame at a distance of at least 5 feet behind the back plumb lines. This background must be free of detail, such as wrinkles, shadows, or lint, that can be seen by both eyes. In front of the observer is an aperture which restricts the binocular visual field strictly to the test elements. Neither the tops and bottoms

of the test elements nor the frame of the cross is to be visible through that aperture.

THE TEST LENS UNIT

Situated before the observer's eyes is a battery of lenses which is used to measure the amount of magnification necessary to correct the anomalous spatial localization and, from this, the type and degree of the ocular-image incongruities (aniseikonia). If one of the test elements of the target appears incorrectly located, the appropriate change is made in the battery until the test element in question appears correctly located. The change in the lenses measures the magnitude of the anomalous-image incongruity.

The battery of lenses is contained in a phorometer-type mount and consists essentially of four units before each eye.* These units will be described according to the sequence of their position before each eye. See figure 2.

(a) Nearest each eye is an adjustable size unit for changing the image size in the horizontal meridian only (axis 90°). The adjustable size unit consists of a telescopelike system of two lens elements, designed in such a way that a change in axial position of one lens relative to the other changes the magnifying effect of the combination without appreciably changing its (zero) verging power. The scale on the circumference of the unit is calibrated to give the percent magnifying power of the unit corresponding to the different separations of the lens components.³

(b) Next is a similar adjustable size unit, one before each eye, for changing the image size in the vertical meridian only (axis 180°).

*The test lens unit described here is the laboratory or experimental model in use at present. Improvements in design are being developed.

(c) Behind these units are four lens cells, two before each eye, for holding individual test size lenses when these are necessary. The cell farthest from the eye in each case can be rotated so as to permit adjustment of the axis of a meridional size lens to any desired meridian.

(d) Finally, there is the front unit for determining whether there is a meridional aniseikonic error at an oblique axis. This

Fig. 2 (Ames). Test lens unit.

consists of two 2.0-percent meridional size lenses, one before each eye, geared so that they rotate together equally but in opposite directions. A handle for rotating the two lenses is attached to the right lens. An indicator and scale engraved in degrees show the rotation of the two lenses from the position where their axes are parallel and vertical. The scale reads only to 45° each way, since the maximum effect occurs at that angle. When the reading is a "positive" angle, the axes of the two lenses will be symmetrically *converged upward*. When the reading is a "negative" angle, the axes of the two lenses will be symmetrically *converged downward*. The angle of rotation is usually designated by ρ (rho).

Fig. 3

Fig. 4

Fig. 5

Figs. 3-5 (Ames). Localization. Fig. 3, Normal localization: normal ocular images. Fig. 4, Anomalous localization: horizontal size difference. Fig. 5 Anomalous localization: vertical size difference.

An interpupillary-distance adjustment screw with scale is provided in the battery mount.

The battery must be kept level. For this

purpose, a small spirit level and adjustment screw are attached to the base of the support.

An adjustable chin cup and forehead

rest are provided for positioning the observer's head.

ANISEIKONIA AND ANOMALOUS APPEARANCE OF THE TARGET ELEMENTS

As an aid to understanding the effect of various types of aniseikonia on the spatial localization of the target elements, there follows a series of illustrations, each of which will present diagrammatically the following objects and methods: (a) the particular type of anomalous incongruity, (b) the means (size lenses) for artificially producing such an incongruity, and (c) the appearance of the elements of the target of the space eikonometer where such an ocular incongruity is present.

Figure 3, as a basis for comparison, diagrammatically illustrates the aforementioned conditions where there is no anomalous incongruity of the ocular images. Drawing A diagrammatically shows the ocular images from the two eyes to be of the same size. (Normally, they are not identical due to the separation of the two eyes.) Nothing appears in the space for drawing B because no size lenses are necessary to produce the normal ocular images. Drawing C shows the normal appearance of the elements of the space eikonometer, all of which lie on planes normal to the binocular line of sight (objective median plane of the observer).

Figure 4 diagrammatically illustrates the phenomena associated with anomalous differences in the size of the ocular images in the horizontal meridian (axis 90°). Drawing A diagrammatically shows the ocular image of the right eye to be larger than that of the left eye in the horizontal meridian. Drawing B shows the types of aniseikonic (size) lenses that artificially produce this type of ocular incongruity (R.E. meridional size lens axis 90° and L.E. plano). Drawing C shows the anomalous appearance of the elements of the target of the space eiko-

nometer. The vertical cords C and H will appear nearer the observer, the cords A and G farther away, and the cross formed by the cords D and F will appear as if rotated about the axis E, with the left side of the cross appearing nearer the observer. The direction of displacement of all the elements will be the same, but the amount of displacement of G and H will be greater than that of D and F which, in turn, is greater than that of A and C.* The magnitude of the anomalous spatial localization is given by the magnitude of the apparent displacement of the elements. If the left ocular image was larger than the right in the horizontal meridian, the anomalous appearances would be of the same nature but in the opposite direction.

Figure 5 diagrammatically illustrates the phenomena associated with anomalous differences in the size of the ocular images in the vertical meridian (axis 180°). Drawing A shows the ocular image of the right eye to be larger than that of the left eye in the vertical meridian. Drawing B shows the type of aniseikonic lenses that artificially produce this type of ocular incongruity (R.E. meridional size lens axis 180° and L.E. plano). Drawing C shows the anomalous appearance of the elements of the target. The vertical cords, A, C, G, and H will appear correctly oriented, but the cross will appear as if rotated about the axis E, with the right side of the cross appearing nearer the observer. If the left ocular image was larger than the right in the vertical meridian, the anomalous appearances would be of the same nature but in the opposite direction.

Figure 6 illustrates the phenomena associated with an overall difference in the size of the ocular images. Drawing A

* This is owing to the fact that, with a given ocular-image incongruity, the apparent displacement of a given configuration increases with distance.

Fig. 6

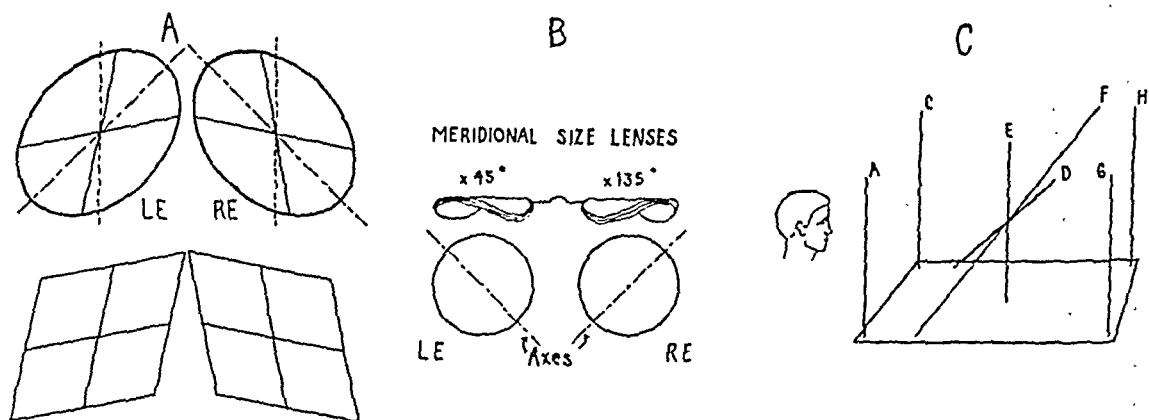

Fig. 7

Fig. 8

Figs. 6-8 (Ames). Anomalous localization. Fig. 6, Overall size difference. Fig. 7, Size difference at oblique axes. Fig. 8, Size difference at oblique axis.

shows the ocular image of the right eye to be larger overall than that of the left eye. Drawing B shows the type of aniseikonic lenses that artificially produce this type of ocular incongruity (R.E., over-

all size lens and L.E. plano). Drawing C shows the anomalous appearance of the target elements. The vertical cords C and H will appear nearer the observer and the cords A and G farther away, but

the cross will appear in its actual position. If the left ocular image was larger overall than the right, the anomalous appearances would be of the same nature but in the opposite direction.

Figure 7 illustrates the phenomena associated with differences in the size of the ocular images in oblique meridians. Drawing A shows the ocular images of both eyes when they are increased in oblique meridians. In this case the images of the vertical meridians of both eyes will be rotated inward at the top. Drawing B shows the type of aniseikonic lenses that artificially produce this type of ocular incongruity (R.E. meridional size lens axis 135° and L.E. meridional size lens axis 45°). Drawing C shows the anomalous appearance of the elements of the target. The vertical cords A, C, G, and H will appear correctly oriented, but the cross will appear tilted away from the observer at the top. If the meridians are rotated in the opposite direction, the cross will appear tilted toward the observer at the top.*

Figure 8 illustrates the phenomena associated with the condition which results when the ocular image of one eye is increased in an oblique meridian at 45° . Drawing A shows the ocular images when the ocular image of the right eye is increased in an oblique meridian at 45° , which causes the image of the vertical meridian of the right eye to be rotated inward at the top. Drawing B shows the type of aniseikonic lenses that artificially produce this type of ocular incongruity (R.E. meridional size lens axis 135° and L.E. plano). Drawing C shows the anomalous appearance of the elements of the target. The vertical cords C and H

appear nearer the observer and the cords A and G farther away. The cross will not appear to be rotated about a vertical axis but will appear tilted away from the observer at the top. (With this condition, the ocular image of the right eye is slightly greater in the horizontal and vertical meridians, and there is a relative declination of the image of the vertical meridian outward at the top.) If the axis of the meridional error were at 90° to that above described, the cross would appear to tilt forward at the top, but the vertical cords would have the same apparent displacement as shown.

Figure 9 illustrates the phenomena associated with the condition which results when the ocular image of one eye is increased in the oblique meridian at 30° . Drawing A shows the ocular images when the ocular image of the right eye is increased in an oblique meridian at 30° , which causes the image of the vertical meridian of the right eye to be rotated inward at the top. Drawing B shows the type of aniseikonic lenses that artificially produce that type of ocular incongruity (R.E. meridional size lens axis 120° and L.E. plano). Drawing C shows the anomalous appearance of the elements of the target. The vertical cords C and H appear nearer the observer, the cords A and G farther away, and the cross will appear to be rotated in the same direction about a vertical axis E, and will also appear to be tilted away from the observer at the top. With this condition, the ocular image of the right eye is slightly greater in the horizontal meridian, and there is a relative declination of the images of the vertical meridian outward at the top. If the axis of the meridional error were at 120° to that aforesaid, the only difference would be that the cross would appear to be tilted forward at the top. (These particular meridians were chosen for this specific example, but

* The direction of apparent tilting of the cross caused by meridional size lenses at oblique axes is opposite to that which would result from viewing a plane surface through the same lenses. Explanation of these phenomena will be dealt with in subsequent papers.

the difference may occur in other oblique meridians, in which case variations and combinations of the appearances will occur.)

Figure 10 illustrates the phenomena associated with the condition that results when the ocular image of one eye is increased in an oblique meridian at 60° .

target elements. The vertical cords C and H appear nearer the observer, the cords A and G farther away, and the cross appears to rotate about a vertical axis E, but in an opposite direction to the displacement of the vertical cords, and also appears to be tilted away from the observer at the top. With this condition,

Fig. 9

Fig. 10

Figs. 9-10 (Ames). Anomalous localization. Fig. 9, Size difference at oblique axis. Fig. 10, Size difference at oblique axis.

Drawing A shows the ocular image of the right eye to be increased in an oblique meridian at 60° , which causes the image of the vertical meridian of the right eye to be rotated inward at the top. Drawing B shows the type of aniseikonic lenses that artificially produce this type of ocular incongruity (R.E. meridional size lens axis 150° and L.E. plano). Drawing C shows the anomalous appearance of the

the ocular image of the right eye is slightly larger in the vertical meridian, and there is a relative declination of the images of the vertical meridian outward at the top. If the axis of the meridional error were at 60° to that aforedescribed, the only difference would be that the cross would appear to be tilted forward at the top. (These particular meridians were chosen for this specific example, but the

difference may occur in other oblique meridians, in which case variations and combinations of the appearances will occur.)

Since these diagrams illustrate specifically the principal types of aniseikonia and the spatial effects associated with them, it will be helpful to describe briefly some of the relationships between combinations of these types of aniseikonia and the appearances of the target elements. It should be borne in mind throughout that the magnitudes of the apparent displacements of the elements increase with an increase in the amount of image size difference. Thus, the greater the size difference between the ocular images in the horizontal meridian, the greater the apparent displacement of the front (and the back) vertical cords. Likewise, the greater the vertical size difference, the greater the apparent rotation of the cross about a vertical axis.

If both the cross and the vertical cords appear to be turned about a vertical axis in the same amount, it means that the size of the ocular image of one eye is larger than that of the other in the horizontal meridian.

If the cross appears to be turned to a greater degree than are the vertical cords in the same direction, it means that the size of the ocular image of one eye is larger in the horizontal meridian and that of the other eye is larger in the vertical meridian.

If the cross appears to be turned to a lesser degree in the same direction, it means that the ocular image of one eye is relatively larger in the horizontal meridian and also in the vertical meridian, but to a lesser degree.

If the cross appears to be turned in the opposite direction to the vertical elements, it means that the ocular image of one eye is relatively larger in the vertical meridian and also in the horizontal meridian, but to a lesser degree.

When the cross does not appear to turn and the vertical elements do, it means that the ocular image of one eye is relatively larger overall than that of the other.

If the cross appears to be tilted away from the observer at the top, it means that the axis of the meridional size correction converges upward toward the median plane (forehead) of the observer.

If the cross appears to be tilted toward the observer at the top, it means that the axis of the meridional size correction converges downward toward the median plane (chin) of the observer.

To summarize, the nature and relative magnitude of the anomalous spatial localization, which is disclosed from the appearance of the space eikonometer target, is directly related to the type and degree of aniseikonia present.

GENERAL PROCEDURE OF THE SPACE EIKONOMETER TEST

With this description of the various types of aniseikonia and their effect on spatial localization, the general nature of the methods used for determining the nature of a subject's ocular incongruity and his anomalous binocular spatial localization will now be considered.

Three types of information can be obtained by means of the space eikonometer with regard to a subject's anomalous spatial localization (aniseikonia):

(1) The appearance to the subject of the elements of the target of the space eikonometer when the adjustable size units are set at zero; that is, are not introducing magnification (size differences).

(2) The nature and magnitude of the magnifications that have to be introduced by means of the size lenses to cause the elements of the target to appear in their proper positions.

(3) The degree of accuracy with which a subject binocularly localizes the various elements of the target, as shown

by the spread of his settings of the adjustable size units when magnifications are introduced to cause the elements of the target to appear in their proper positions.

The general procedure for obtaining this information is as follows:

The subject, wearing his distance refractive correction (if ametropic) in a trial frame or spectacles, is seated before the instrument with his head properly positioned in the headrest. The examiner adjusts the test lens units for interpupillary position and makes certain that the subject can see both of the front green plumb cords with each eye.

It is then explained to the subject that this is a test involving binocular space perception and that the test elements of the instrument will be seen to change their positions during the different parts of the test when certain lenses are used and that he (the subject) will be asked to make accurate judgments as to their relative distances and positions. While the examiner calls attention to the test elements and their behavior, he gradually changes the size of the image of one eye and then that of the other by means of the adjustable size units, first in the horizontal meridian (axis 90° unit), then in the vertical (axis 180° unit), and then in oblique meridians (geared lens unit). This series of changes in image size with the corresponding changes in apparent orientation of the test elements serves both to acquaint the subject with the nature of the test and to arouse his stereoscopic perception. (It is well to bear in mind that aniseikonic patients frequently have binocular fusion difficulties and may be relatively insensitive to stereoscopic clues.)

The adjustable size units are then set at "zero" and the subject is questioned as follows: "Do the two front green cords appear the same distance from you or is

one nearer? If one is nearer, which one—the right or left?" "Does the cross, when considered as a whole, appear rotated about the central white cord, with one side nearer to you than the other, or are the two sides at the same distance from you?" If they are not at the same distance, the subject is instructed to estimate whether the apparent rotation is equal, greater, or opposite in direction to the apparent rotation of the two front green cords. "Does the cross, when considered as a whole, appear to be vertical, or is it inclined with the top toward or away from you?"

The subject's answers to these questions may be entered on the data sheet as a qualitative record of the nature of his anomalous localization.

Using the same form of questioning, the examiner then proceeds to determine the magnitude of the false orientation of the test elements in terms of the image size difference (magnification) which it is necessary to introduce to correct the false orientation. The basic principle to be observed is to measure and correct the size difference in the horizontal meridian (axis 90° unit) before proceeding with the measurement of the vertical size difference.

Axis 90° measurements (image size differences in the horizontal meridian). The subject is instructed to report which of the two front vertical cords appears nearer—the right or the left. If the right cord appears nearer, magnification is introduced in the adjustable size unit (axis 90° unit) before the right eye until it is reported that the cords are equidistant. If the left cord is reported to be nearer, the image size in the left eye is increased in the horizontal meridian.

The rule, then, in making axis 90° determinations, is to increase the magnification before the eye corresponding to the nearer cord. The nearer cord will be on

the side of the eye having the smaller ocular image (in the horizontal meridian).

At this point the accuracy, or sensitivity, of the subject's discrimination can be checked by determining how much magnification, more or less, can be introduced before the lines no longer appear equidistant.

For convenience and consistency, all measured image incongruities (axis 90° , axis 180° , and oblique), should be recorded in terms of the magnification of the size lenses which is necessary to correct the false appearances of the test elements. Thus, R. 3.00% $\pm 0.25\%$ ax. 90° means that a 3.00 percent meridional size lens at axis 90° before the right eye was necessary to make the two front vertical cords appear the same distance from the observer and that the observer could discriminate this difference with a sensitivity of ± 0.25 percent. Of course, the left ocular image is actually 3.00 percent larger in the horizontal meridian. For comparison with the subject's symptoms and performance, however, it is usually better to think in terms of which of the ocular images is larger or smaller, instead of in terms of the correction.

Axis 180° measurement (size differences in the vertical meridian). With the axis 90° size correction in place, the subject is now instructed to report which side of the cross appears nearer to him—the right or the left. If the right side of the cross appears nearer, magnification is introduced in the vertical meridian (axis 180° size unit) before the left eye until both sides of the cross are reported to be equidistant. If the left side of the cross is reported nearer, the magnification must be increased in the axis 180° unit before the right eye.

The rule, then, in making axis 180° measurements is to increase the magnification before the eye corresponding to the

farther side of the cross. The nearer side of the cross will be on the side of the eye having the larger ocular image (in the vertical meridian).

The accuracy of the subject's judgment can be determined in the same manner as described in the preceding section.

The presence of a vertical phoria will frequently change the appearance of the cross in such a way that the two oblique cords do not appear to intersect, one of the cords appearing closer to the subject than the other. In this event it is necessary to correct the vertical phoria by means of prisms before making the measurements.

An overall difference in the size of the ocular images occurs when, in the absence of an oblique error, the axis 90° and axis 180° corrections before one eye are found to be equal.

Measurements to determine the image size differences in oblique meridians. With both the horizontal and vertical size differences corrected, the subject is instructed to report whether the top of the cross appears to tilt toward or away from him. If the top is reported to tilt forward, the geared lenses are rotated toward the minus side of the scale (axes converging down) until the cross is reported to be vertical. If the top of the cross is reported to tilt away from the subject, the geared lenses are adjusted to the plus side of the scale (axes converging up) until the cross is reported to be vertical.

The accuracy of the subject's discrimination can be checked by determining the limits in degrees of rotation of the geared lenses within which the cross is reported to be vertical.

At this point the axis 90° and axis 180° findings should be rechecked. This is done to eliminate the possible influence of the apparent position of the cross upon the cords, and vice versa. The subject should then be questioned as to whether

the elements of the target as a whole appear correctly oriented.

Ordinarily for prescription purposes, it is sufficient to designate the correction in terms of the axis 90° and axis 180° findings in percent magnification and the oblique findings in terms of degrees of rotation of the geared lenses. From these data the lens designer can determine the aniseikonic correction.

It is worth while, in the test, to determine the equivalent prescription of meridional size lenses which corrects the axis 90° , axis 180° , and oblique incongruities as determined by the foregoing procedure. For this purpose, a series of tables have been computed.⁶ When this equivalent correction is found, the indicated size lenses may be placed before the eyes. The adjustable size units and the geared lenses are then set back to "zero" and the subject is instructed to report on the appearance of the target elements. If the data and equivalent lens combination have been determined correctly, the equivalent lenses should correct the ocular incongruities present, and all of the elements of the target should appear properly oriented.

Irregular and asymmetric incongruities. Thus far, only regular, systematic ocular incongruities have been considered. There is evidence, however, that irregular incongruities, which may be due either to anomalous dioptric conditions or an anomalous anatomic organization of the retinal elements, are not uncommon and can exist in combination with one or more types of regular ocular incongruities. For instance, the ocular image from the right eye may be larger than that from the left in the horizontal meridian at one angular distance and smaller at another. The presence of such irregular incongruities does not make itself apparent in the appearance of the elements of the space eikonometer. It may result, however, in a

decreased sensitivity and in the inability to perceive any or the proper amount of displacement of the elements of the target when artificial incongruities are produced by means of size lenses. No means of measurement or correction of such incongruities are available as yet.

Another type of aniseikonic error which may be more or less systematic in character is that produced by an anomalous asymmetric incongruity of the two ocular images. One form, not infrequently encountered, is an anomalous horizontal incongruity of the two ocular images where the images from the nasal sides of the retinas are greater than those from the temporal side (that is, temporal field larger than nasal). To the observer with such a condition a flat surface situated normal to him, may appear to be convex toward him or flat and nearer. If the asymmetric incongruity is greater temporally than nasally, the surface may appear either concave or flat and farther away. At present, methods of determination and correction of this type of incongruity are being studied.

Asymmetric incongruity can be in meridians other than the horizontal meridian and in one eye only. Such types of anomalous asymmetric incongruity make themselves apparent in the anomalous appearances of the elements of the cross, as when one or more of the arms are tilted backward or forward from the plane of the cross. The exact nature of these types of asymmetric incongruity requires further study.

DISCUSSION

The space eikonometer has been in daily use in the Clinical Division of the Dartmouth Eye Institute since July, 1941. During this time it has been possible to evaluate the test from the standpoint of practical clinical application.

Quite early in the investigations it was

established that a high correlation existed between the measurements of aniseikonia obtained with the standard eikonometer and those obtained by anomalous space perception on the space eikonometer.⁷

This actually should be interpreted as a validation of the principle of the standard eikonometer procedure, since anomalous binocular space perception can be accounted for only in terms of image size differences and not in terms of anisophoria or differential fusional movements of the eyes as has been suggested⁸ with regard to the standard eikonometer findings.

Clinical experience has shown that, in general, the space-eikonometer-test procedure consumes considerably less time and provides an easier discriminative task for the patient than does the standard eikonometer procedure. Such factors as fixation disparity, phoria variability, and poor fixation ability, which make discrimination a difficult task for many patients during the latter test, do not enter into the space eikonometer test to complicate the procedure. Certain exceptions exist, however. Patients who have binocular vision but no stereopsis can usually be handled more satisfactorily with the standard eikonometer.

It must be emphasized, however, that the ordinary tests for stereopsis do not provide criteria for determining whether the patient may or may not be measured on the space eikonometer. Individuals with little or no central (axial) stereopsis can be measured on the space eikonometer with considerable accuracy provided they manifest peripheral stereopsis.

Over and above these obvious practical advantages the space eikonometer provides a means for determining meridional aniseikonia at oblique axes. It should be pointed out here that the majority of cases with astigmatism at oblique axes can be expected to demonstrate a meas-

urable amount of this form of aniseikonia.⁹ Cases have been studied in which the full astigmatic (oblique) correction could be tolerated only when the associated aniseikonia was also corrected.¹⁰ It is common clinical experience to have patients with astigmatism at oblique axes report various distortions of their environment following correction of their refractive error. With constant wearing of the correction these distortions often disappear after a few days. It has been customary to assume that their disappearance represented simply an adaptation to the new correction.

It must be borne in mind, however, that the usual surroundings contain an abundance of uniocular clues to spatial orientation (rectilinear perspective, size, brightness, shadows, familiar forms, and the like) to which the individual may respond. That he does so is evidenced from the fact that even after "adaptation" has taken place, the spatial distortions immediately become manifest when he is placed in surroundings lacking in uniocular clues.⁴ Such surroundings may be natural, as in the woods, open country, or on the water, or artificial, as in the environments provided by aniseikonic test apparatus in which they can be measured. Unless the aniseikonic errors are corrected there remains, in spite of this "adaptation" to normal surroundings, a basis for conflict between the responses to the uniocular and binocular clues which can be troublesome and productive of further symptoms. The "adaptation," then, simply means that the patient is not utilizing binocular vision with full efficiency, but is disregarding binocular stereoscopic clues and relying predominantly upon uniocular clues for spatial orientation.

From such considerations it may be concluded that interpretation of the nature of the patient's anomalous spatial

localization provides a basis for a clearer understanding and evaluation of the patient's symptoms in terms of his actual function and performance. From the point of view of efficiency of function, in so far as there is any disregarding or suppression of the binocular stereoscopic clues, the accuracy of the patient's binocular spatial localization is, to that extent, impaired.

It should be emphasized here that this impairment represents, in essence, a lack of correspondence between the visual localization and the actual location of the external environment. Considered from the standpoint of stimulus-response relationships and the role of sensory impressions as determinants of behavior, this clearly becomes a matter of broad, general sig-

nificance. The inadequacies and errors in performance resulting from such lack of correspondence can have a profound effect upon the individual in providing a basis for conflicts and frustrations. The nature and severity of the effects vary with the individual and are conditioned by such factors as the nature of his visual environment, the nature of the visual requirements of his occupation, his general motivation, and his health. Thus, not only do our concepts of the functional aspects of aniseikonia become clarified but an analytic approach is indicated which should be helpful to the clinician when utilized in diagnosis and considerations of therapy.

PERFORATING OCULAR INJURIES*

ALBERT C. SNELL, JR., M.D.

Baltimore

This report is based on a study of the records of 172 cases of perforating ocular injuries of patients who were admitted to the wards of the Wilmer Ophthalmological Institute during the years 1935 to 1942, inclusive.

The selection of these 172 cases was made from a total of approximately 275 both public and private ward patients. Some records were discarded either because they were incomplete or because there was an inadequacy of postoperative follow-up observation. Also discarded were the records of all patients with perforating ocular injuries who had received definitive treatment before coming to the hospital, or in whom examination had been so long postponed that the outcome was determined before treatment could be instituted. The study does not include nonperforating injuries, or cases of subconjunctival scleral rupture. Cases of retained intraocular foreign bodies are included. Of the 275 records which were reviewed, 47, or 17 percent, were discarded because enucleation was performed without any attempt being made at repair, it being considered that the eyes were hopelessly lost. Figures including these 47 enucleated eyes, however, appear later in the discussion of the influence of the length of the laceration on recovery, and in the computation of the incidence of sympathetic ophthalmia.

In this study there are no rigid specifications of minimal postoperative observation; thus there are included all records in which it seemed reasonably cer-

tain that the visual acuity had reached its final level at the time of the last recorded examination. This method of selection may have led to the occasional inclusion of a case as a "successful" result which may later have developed serious complications. On the other hand, there are included a few cases in which further operative treatment (for example, discission or capsulectomy) might have produced an improvement of the final visual acuity.

Applying these methods of selection, there are available for review the records of 172 cases of recent perforating ocular injuries, in each of which an attempt was made to save the eye.

The cases were analyzed and, as far as possible, studied statistically in the attempt to illuminate the following problems:

- A. What average degree of success was achieved?
- B. What are the principal complications that influence the outcome?
- C. What are the best methods of management?

Each of these items is discussed below under separate headings.

AVERAGE DEGREE OF SUCCESS

The degree of success expressed in final visual acuity achieved in the treatment of these injured eyes is given in table 1. Fifty-two patients, or 30 percent, regained a corrected visual acuity of 20/40 or better. (There are 12 cases in which the visual acuity could not be measured because the patients were too young to coöperate. In these cases the final examination disclosed nothing that should interfere with visual acuity. These cases are included in the 20/100 column in all tables.) In 47 cases the end result was loss of all light perception, enucleation

* From the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital and University. Presented in part before the New York Academy of Medicine, Section of Ophthalmology, Dec. 20, 1943.

TABLE 1
OUTCOME AS TO VISUAL ACUITY WITH CORRECTION—172 CASES

Visual Acuity	20/20 to 20/40	20/50 to 20/100	20/200 to 10/200	9/200 to 1/200	Light Projection	Light Perception	Blind
Number of each	52	34*	7	18	5	9	47**
Percent	30	20	4	11	3	5	27

* Includes 12 cases in which the visual acuity could not be measured.

** 44 of these were enucleated.

being performed in 44 of these. There remain 39 cases in which the final visual acuity varied from 20/200 to the ability to perceive light. In this series, the visual-acuity figure is an accurate index of the usefulness of the injured eye, there being no case in which there was extensive loss of the visual field without associated reduction of central vision.

Thus, in the treatment of the 172 cases of perforating ocular injuries, 50 percent of the patients achieved a final visual acuity of 20/100 or better, and 50 percent of 20/200 or worse.

THE INFLUENCE OF COMPLICATING FACTORS

In perforating ocular injuries there are numerous factors and complications that may influence the final visual outcome. A complete study of the role and the interrelationship of each of these numerous possible variables in the course and outcome of such injuries is impossible in a clinical series of this size. Nevertheless, it is important to break down the over-all

figures in a study of the role of a few factors which, on the basis of general experience, are presumed to be important. This has been done for the following factors and complications: (1) the age of the patient, (2) the agent causing the injury, (3) the length of the laceration, (4) the location of the laceration, (5) the degree and nature of prolapse of intraocular contents, (6) the degree of damage to the lens, (7) the degree of intraocular hemorrhage, (8) the occurrence of infection, (9) the occurrence of sympathetic ophthalmia, and (10) the presence or absence of retained intraocular foreign bodies.

(1) *Age.* The age distribution for the 172 cases analyzed is shown in table 2. The patients of 40 years or over are grouped together because of their relatively small number. In this table there are no striking variations in the average levels of visual acuity achieved in the various age groups, except that the figure of 36 percent regaining 20/100 corrected vision or better for the group 40 years

TABLE 2
OUTCOME IN VISUAL ACUITY ACCORDING TO AGE

Age yrs.	No.	20/20 to 20/40	20/50 to 20/100	20/200 to 1/200	Light Perception	Blind	20/100 or Better, percent
0-4	18	1	7	—	1	9	44
5-9	31	13	3	5	1	10	50
10-19	47	17	4	10	1	11	51
20-29	24	8	6	4	3	3	58
30-39	27	10	5	—	4	8	54
40+	25	3	6	6	4	6	36

and over is lower than the average. For old individuals, it might be assumed that such factors as delay and imperfection in healing, or increased vascular fragility, or diminished resistance to infection contribute to a poorer average of satisfactory recoveries. However, in the 25 cases falling in the age group of 40 years or over, reopening of the wound or delay in re-formation of the anterior chamber occurred in three cases, unusual hemorrhage occurred in three cases, and intraocular infection occurred in four cases, with one

ly little maceration of tissue. The same principle apparently applies in this series to perforating injuries by wooden splinters.

The few instances of gunshot wounds indicate that this type of perforating ocular injury has a poor prognosis, undoubtedly because of the disorganization of the ocular tissues secondary to the explosive force of bullet impact, and the usual double perforation of the globe. Blunt injuries appear to carry a poor prognosis; often trauma from a blunt

TABLE 3
OUTCOME ACCORDING TO THE AGENT CAUSING THE INJURY

Agent	No.	20/20 to 20/40	20/50 to 20/100	20/100 to 1/200	Light Perception	Blind	20/100 or Better, percent
Glass	43	16	13	4	4	6	67
Wood	27	12	4	3	2	6	59
Metal	63	15	13	9	4	22	44
Blunt	8	1	2	2	0	3	38
Gunshot	6	1	0	1	1	3	17
Miscellaneous, unknown	25	7	2	7	3	6	35

recovery. The incidence, for this age group, of each of the aforementioned complications is similar to that for the entire series (see below). The data do not show an influence of the age of the patient on recovery. The possible effect of senility cannot be determined because of the small number of older patients.

Recapitulation: The age of the patient is not demonstrated to have an influence on the outcome in terms of visual acuity. The data are inconclusive because of the limited number of persons of advanced age.

(2) *Agent.* The data as to the influence of the agent causing the injury on the final outcome are given in table 3. Lacerations caused by glass appear to have the best prognosis, most probably because such lacerations are usually very clean and straight, and are associated with relative-

object (brick, fist, and so forth) ruptures the globe, owing to its explosive force. Moreover, a direct laceration from a blunt object is very apt to have ragged and macerated margins.

Recapitulation: The influence on the outcome of the agent causing the injury appears to be roughly proportional to the sharpness of the agent. Bullet wounds and blunt injuries carry a poor prognosis.

(3) *Length of laceration.* Table 4 shows the outcome in visual acuity following lacerations of various lengths. To eliminate some variables, there are included in table 4 only cases of corneal or of corneoscleral lacerations, and those of retained intraocular foreign bodies are excluded. Thus, it is seen in table 4 that when the visual results are grouped as better or worse than 20/100, there is no striking relationship between the length

of the laceration and the average outcome in terms of visual acuity. However, if the cases are grouped as better or worse than 20/40 visual acuity, it is seen that the number regaining normal or nearly normal vision falls off steadily as the length of the laceration increases. Evidently the longer the corneal scar the greater is the chance it will interfere with vision, even

tions, the data concerning the influence of the length of the wound on the final outcome demonstrate the following points:

First, lacerations of 1 to 4 mm. in length are nearly as dangerous as lacerations of 5 to 8 mm.

Second, there are several instances of recovery from lacerations over 8 mm. in length, which demonstrates that satisfac-

TABLE 4
OUTCOME ACCORDING TO THE LENGTH OF THE LACERATION*

Length mm.	No.	20/20 to 20/40	20/50 to 20/100	20/200 to 1/200	Light Perception	Blind	20/100 or Better percent	20/40 or Better percent

9 and over	14	2	4	—	4	4	43	14

* Corneal or corneoscleral lacerations only, excluding cases with retained intraocular foreign bodies.

though healing proceeds satisfactorily in all other respects.

It must be realized that in this series a strong element of selection operates as far as the length of the laceration is concerned. The amount of organic damage done to eyes is often pertinent to the length of the laceration—in general, short lacerations tend to produce less organic damage than do long lacerations. Since the decision to enucleate or not to enucleate an injured eye is based on the clinical picture and the amount of organic damage produced by the injury, in general, eyes that have long lacerations are enucleated more frequently, no attempt being made at repair, than are eyes with short lacerations. Thus of the 47 eyes enucleated immediately, without attempt to repair, 80 percent had lacerations of 8 mm. or over. This automatic exclusion of a great number of eyes with long lacerations, weights the figures in this study in favor of short lacerations.

With due allowance for these limita-

tory healing may occur in the presence of long lacerations. (On the other hand, there is every reason to believe that a great majority of the eyes with long lacerations which were enucleated immediately would not have healed satisfactorily had repair been attempted.) On the basis of these observations, it is reasonable to assume that it is such factors as the degree of the explosive force of the blow or of the severity of intraocular hemorrhage that are the determining factors, and the actual length of the laceration is only incidental.

Recapitulation: No correlation is demonstrated between the length of the laceration and the percentage of satisfactory recoveries for wounds under 9 mm. in length. The data are severely influenced by the tendency to enucleate immediately nearly all eyes that have sustained a long laceration.

(4) *Location.* In table 5 are presented the data on the outcome correlated with the location of the laceration. Forty-seven

TABLE 5
OUTCOME ACCORDING TO THE LOCATION OF THE LACERATION

Location	No.	20/20 to 20/40	20/50 to 20/100	20/200 to 1/200	Light Perception	Blind	20/100 or Better, Percent
Cornea	114	35	19	20	7	33	47
Ciliary body	15	8	1	4	0	2	60
Cornea and Ciliary body	31	8	10	1	3	9	58
Sclera	6	2	2	—	1	1	67
Double perforation	6	—	1	1	2	2	17

percent of the eyes in which the laceration was confined to the cornea achieved a visual acuity of 20/100 or better. Involvement of the sclera in the region of the ciliary body, with or without extension into the cornea, does not have an adverse influence, since 58 percent of eyes with such lacerations regained visual acuity of 20/100 or better. Perforating lacerations posterior to the ciliary body are less frequent, occurring only six times in this series, and no conclusions can be drawn as to the relative seriousness of such injuries. Double perforations of the globe apparently rarely heal with retention of useful vision, although the number of such cases is so small the data are of no statistical significance.

Recapitulation: The location of the laceration is not demonstrated to have an effect on the average of successful recoveries. A double perforation of the globe appears to have an unfavorable effect.

(5) *Prolapse.* The disorganization produced in the eye by severe degrees of prolapse of the intraocular contents is so obvious that it needs no further discussion. When serious degrees of prolapse are met with in perforating ocular injuries, the picture is so evidently hopeless that it is only exceptionally that any attempt at repair is undertaken. The effect of major degrees of prolapse is agreed to be devastating and needs no further demonstration. It is, however, of interest to

assess the not-so-obvious influence of minor degrees of prolapse.

Prolapse of the iris in a corneal laceration has often been regarded as a natural defense mechanism against infection. Is this concept in accord with the findings for this series? There are in this series 145 cases of corneal laceration, including those extending into the sclera. Prolapse of iris or ciliary body occurred in 91 of these cases; and in 54 there was no prolapse of iris or ciliary body. Of the 91

TABLE 6
THE EFFECT OF PROLAPSE OF IRIS UPON THE DEVELOPMENT OF INFECTION

Prolapsed	38	21	53	3.8
Not prolapsed	33	33	21	19

eyes in which prolapse of iris or ciliary body occurred, 12, or 13 percent, developed an intraocular infection. Of the 54 uncomplicated by prolapse, 15, or 28 percent, developed an intraocular infection (table 6). The figures suggest that the incidence of infection complicating corneal wounds is reduced by the presence of a prolapse of the iris. However, since there is a correlation between infection and injury of the lens, the incidence of lens damage is also shown in table 6. Again, there is an apparent antiseptic effect of prolapse of the iris, but the figures fall short of statistical value.

TABLE 7

OUTCOME ACCORDING TO THE OCCURRENCE OF PROLAPSE OF IRIS*

Iris Involvement	No.	Average Length mm.	20/100 of Better, percent	Blind, percent
Prolapsed	60	5.1	60	15
Not prolapsed	28	4.5	71	11

* Corneal or corneoscleral lacerations, not infected, excluding cases with intraocular foreign bodies.

It remains to be seen if prolapse of the iris has any further significance as regards recovery from corneal wounds. In an effort to isolate as much as possible the role of prolapse of the iris, those cases complicated by infection or by retained intraocular foreign bodies were for the moment discarded. This left 88 cases of corneal or corneoscleral lacerations, in 60 of which there was prolapse of iris, and in 28 no prolapse. Table 7 indicates that recovery of vision is little influenced by the occurrence of prolapse of the iris, in the absence of infection.

Prolapse into a corneal wound of lens material with or without uveal tissue occurred 10 times. Six of these eyes ultimately were removed, and only one regained visual acuity of 20/100 or better. These figures may not be significantly different from those given in table 8, which shows the degree of success achieved in the presence of injury to the lens, with and without prolapse of lens substance.

Recapitulation: Prolapse of the iris in a corneal laceration is not observed to influence the outcome; its occurrence is not demonstrated to be associated with a reduced incidence of infection, although there is suggestive evidence of such an effect.

(6) *Lens damage.* The data showing the influence of damage to the lens in perforating ocular injuries are given in table 8. Of 73 eyes in which the lens remained intact, 75 percent regained a final corrected visual acuity of 20/100 or better, and 14 percent eventually came to enucleation. On the other hand, of 56

TABLE 8

OUTCOME ACCORDING TO THE OCCURRENCE OF INJURY TO THE LENS*

the period of observation, presumably because of some secondary influence. Those cases involved by intraocular foreign bodies are not included.

These data indicate a malignant effect of traumatic cataract in cases of perforating ocular injuries. They raise the question of how a pathogenetic effect is exercised by the damaged lens. This problem was attacked first, by a study of the causes of reduction in visual acuity in eyes removed, comparison being made in each instance of the eyes that had suffered lens damage with those in which the lens was uninjured.

The histologic findings of the enucleated eyes are given in table 9. To reduce the number of possible variables, cases complicated by an intraocular foreign body are excluded. In comparing the findings according to the presence or absence of lens injury, two important differences stand out: First, the number of eyes lost through infection, and, second, the incidence of posttraumatic uveitis are both greater among those eyes which received damage to the lens. The question of infection is discussed more fully below. However, attention is here called to table 13, which shows the incidence of purulent infection for the entire series, and its much more frequent occurrence among cases complicated by injury to the lens.

Turning aside for the moment from the question of purulent infection, it was noted in the foregoing account that the occurrence of posttraumatic uveitis appeared to be favored by the presence of damage to the lens. To determine to what extent lens damage could be responsible for this posttraumatic uveitis, comparison of the incidence of posttraumatic uveitis in retained eyes, in the presence and in the absence of lens damage, was made, and is shown in table 10. Since the role of purulent infection has already been demonstrated, all instances of clinical evidence

of infection are omitted in table 10, which refers only to corneal and corneoscleral lacerations, cases in which there were intraocular foreign bodies also being ex-

TABLE 10

INCIDENCE OF POSTTRAUMATIC UVEITIS*

Lens injured, 31 cases	9	3	1

* Excluding instances of purulent infection, or of intraocular foreign bodies, and not including enucleated eyes.

cluded in an effort to isolate the variable under consideration. It is seen that posttraumatic or postoperative uveitis occurred in 12 of 31 cases in which there was traumatic cataract, and occurred in no instance among those 78 cases in which the lens was intact (including cases with nonprogressive lens opacities or with late lens changes). The classification of uveitis phaco-anaphylactica rests upon the demonstration of an abnormal skin sensitivity to lens protein on intracutaneous injection. One instance of uveitis was almost certainly sympathetic ophthalmia, as demonstrated by a granulomatous uveitis of the second eye coming on 14 weeks after injury, in association with a positive skin test for uveal pigment. The occurrence of uveitis contributed to a reduction in visual acuity in a number of cases (table 11). Perhaps a more serious attribute of the complication is that it suggests the danger of sympathetic ophthalmia and encourages enucleation. In this way, a relatively benign posttraumatic iritis may cause the loss of an eye which otherwise might have recovered.

It is thus seen that the complication of injury to the lens contributes to unsatisfactory healing in two respects: It in-

creases the incidence of purulent intraocular infection, and it increases the incidence of posttraumatic uveitis. It remains to be seen if these sources of failure comprise in full the pathogenetic effects of the damaged lens. With this end in view, table 11 has been constructed, giving the cause for reduction of vision (below 20/40) in surviving eyes, again excluding cases complicated by infection or by retained intraocular foreign bodies, and in-

Recapitulation: Injury to the lens exerts an adverse influence on the final visual outcome. Its principal deleterious role lies in the tremendously increased incidence of purulent infection and of posttraumatic uveitis. In the absence of these complications, injury to the lens does not influence the prognosis for recovery of vision.

(7) *Hemorrhage.* Minor degrees of hemorrhage into the anterior chamber or

TABLE 11
CAUSE FOR REDUCTION OF VISUAL ACUITY*

* Corneal or corneo-scleral lacerations, not infected, without intraocular foreign body.

cluding corneal or corneoscleral lacerations only. In table 11, the increased incidence of visual failures among cases presenting an injured lens is accounted for almost completely by two factors; first, by several instances of post-iritis changes (synechiae, occluded pupil, cyclitic membrane, and the like) sufficient to cause reduction of vision; and secondly, by opacities derived from the remains of incompletely removed traumatic cataract.

On the whole, there are three reasons why injury to the lens is associated with such a less-favorable, average outcome—incomplete removal of a traumatic cataract, and the complications that follow either a purulent infection or a post-traumatic uveitis. If these complications do not develop, the chances of recovery of vision in perforating ocular injuries are equally good regardless of the occurrence of traumatic cataract.

into the vitreous were not demonstrated to have any relation to the final visual outcome. For the sake of simplicity these data are omitted. There are 18 cases in this series in which severe intraocular hemorrhage was devastating. Three of these cases were further complicated by an intraocular infection, leaving 15 cases for analysis.

Of the 15 uninfected eyes which sustained severe intraocular hemorrhage, 8 were eventually enucleated. One of these developed sympathetic ophthalmia, and it is possible that hemorrhage may have had some influence on the outcome, since a severe intraocular hemorrhage, occurring on the third postoperative day, resulted in secondary glaucoma, which was treated by lavage of the anterior chamber. Two cases showed, in addition to the hemorrhage, a subacute inflammatory reaction that kept the eyes dangerously irri-

tated for several days after repair, so that they were enucleated as potentially sympatheticogenic. One of these two had sustained a through-and-through injury from a knife, and a cilium was discovered in the posterior wound. Two others were in phthisis at the time of enucleation. In the sixth case there was a badly disorganized globe. In the remaining two, there was massive subretinal hemorrhage; one of these eyes was enucleated because of a painful secondary glaucoma and another because it failed to clear after repair and was considered potentially dangerous.

Of the seven eyes that sustained severe intraocular hemorrhage and were not enucleated only one recovered useful vision. Three developed phthisis bulbi. None of these three received any second operation which might have contributed an added insult. In two, haziness of the vitreous persisted and reduced vision to light perception with accurate projection. One of these had a through-and-through laceration, evidenced by roentgenographic demonstration of a foreign body in the orbit. The other had a short corneal laceration without evidence of damage to the lens, in which a severe vitreous hemorrhage did not clear in 70 weeks. In one a cyclitic membrane developed across the pupillary space.

These cases illustrate well three disastrous effects of intraocular hemorrhage. In the first place, hemorrhage has a tremendous disorganizing effect, dislocating the intraocular contents and often sweeping them out through the laceration, as in an operative expulsive hemorrhage. Secondly, intraocular hemorrhage has an irritative effect, exciting an inflammatory response which is always alarming, and occasionally ends with the formation of a cyclitic membrane and phthisis bulbi. In the third place, for little-understood reasons, hemorrhage in the anterior chamber instead of becoming absorbed may proceed to organization, with the formation

of heavy scars obliterating the pupil and the chamber angle, and in the vitreous chamber may produce destruction of the retina and detachment.

Intraocular hemorrhage is, in all likelihood, frequently responsible for the quiet passing into phthisis of many injured eyes whose original appearance had encouraged optimism. An inconspicuous posterior-chamber hemorrhage, for example, may give rise to a low-grade iritis, or may organize and initiate a cyclitic membrane; or an overlooked choroidal hemorrhage may end in retinal detachment, and so forth.

Recapitulation: It is evident that severe intraocular hemorrhage is usually recognizable clinically, and produces such a serious picture that the eyes are often promptly removed. The outlook for recovery of vision in those that are treated surgically is poor, for the following reasons: (a) The disorganizing effect of intraocular hemorrhage, (b) the irritating effect of and inflammatory reaction to hemorrhage, and (c) the occasional tendency of hemorrhage to organize.

(8) *Infection*. Microscopic examination of the 44 enucleated eyes showed positive evidence of intraocular infection in 17, the largest single pathologic finding in the group of enucleated eyes. In nine other cases, definite clinical evidence of infection was present, although histologic proof was lacking because enucleation was not performed (five cases), or because the process had passed through the stage of purulent inflammation by the time of enucleation (four cases).

The clinical evidence for the presence of infection in the nine cases wherein histologic demonstration was lacking is as follows: Of the five eyes which were not enucleated, two had a corneal abscess at the site of the perforation with hypopyon; one had frank pus in the anterior chamber; and the other two had clinical evidence of a less severe purulent intraocu-

lar reaction. Of the four eyes which were removed after passing through the stage of purulent reaction, one had a hypopyon of the anterior chamber and *B. subtilis* was cultured from the discharge before repair; one was described as "a severe intraocular infection," and *B. coli* was cultured clinically; one was described as "grossly infected," with a heavy growth of *Staph. aureus* on culture, and the fourth had purulent exudate in the anterior chamber, with a heavy growth of *Staph. aureus* on culture. On pathologic examination of these four eyes after enucleation, three showed subacute intraocular inflammation, not purulent in type, and similar to that occurring in untraumatized eyes with severe uveitis. The sections of the eye from the fourth case showed phthisis bulbi with a cyclitic membrane, and practically no active inflammation.

The subsidence of an acute purulent endophthalmitis without perforation and the progress of the eye into phthisis is, of course, an old observation. It is further exemplified in this study by two other cases. In both of these iridectomy was performed at the height of the inflammation and the biopsy specimen from the iris showed acute purulent inflammation. The eyes later came to enucleation and both showed phthisis bulbi with little active inflammatory residue.

Seven of the 44 enucleated eyes showed, on the microscopic sections, a subacute type of intraocular infection, although there was no clinical nor bacteriologic evidence of purulent inflammation. Since there is no way of determining with certainty whether these eyes were the site of a traumatic uveitis or a low-grade infection, these eyes cannot be classified as "infected," although this etiology cannot be ruled out.

The incidence of infection in the entire series of 172 cases was 26 cases, or

15.1 percent. Among the 47 eyes which were enucleated after the first examination without any attempt at repair or treatment, purulent endophthalmitis was present in 11. The incidence of infection for the total 275 injured eyes from which the material was selected was 40, or 14.5 percent.

The seriousness of infection complicating penetrating injuries is shown in the fact that of the 26 cases in which this diagnosis was made clinically or pathologically all but 5 eyes were enucleated. Of the five eyes that were retained, one ended with loss of all light perception. In the remaining four eyes, all of which recovered good vision, two had corneal abscess with hypopyon. While the clinical picture indicated that infection actually was present within the eye, it is possible that in these cases the infection was restricted to the cornea and the intraocular contents were not invaded. Of the two eyes in which recovery from a clinically diagnosed purulent endophthalmitis occurred, both received intensive therapy, one with sulfathiazole and one with sulfapyridine. Thus, of the 26 eyes in which the diagnosis of purulent endophthalmitis was made, 22 lost all vision, and 4, or 15 percent, regained 20/40 vision or better.

The influence of the sulfonamides in the treatment of intraocular infection following penetrating injuries is shown in table 12. Thirteen patients received intensive treatment by the oral use of one of the sulfonamides, and of these three recovered. Thirteen others were not so treated, and of these one recovered. These data indicate that the sulfonamides, while probably of great value in a few cases, are on the whole unsatisfactory in the treatment of intraocular infections complicating penetrating ocular injuries.

There is long-standing, well-documented evidence that lens cortex acts as an

TABLE 12

SULFONAMIDES IN THE TREATMENT OF PURULENT INTRAOCULAR INFECTIONS FOLLOWING PENETRATING INJURIES

Drug	No.	Days from Injury to Onset of Treatment	Duration of Treatment, days	No. with Lens Damage	Enucleated	Recovered

TOTAL TREATED	13			11	10	3
NO SULFONAMIDE TREATMENT	13			9	11	1

excellent culture medium for bacteria of all degrees of virulence, and that damage to the lens in a perforating ocular injury greatly enhances the occurrence of intraocular infection. The findings in this study are in no way at variance with this principle, as shown in table 13. Of the 26 eyes in which the diagnosis of purulent inflammation was made, 20 sustained damage to the lens and 6 did not. Conversely, for the whole series without regard to the presence or absence of other complicating factors, 78 eyes received damage to the lens and 26 percent of these were infected, while 94 had no damage to the lens, and of these only 6 percent were infected.

Fifty-six of the patients in this study received either sulfathiazole or sulfadiazine as a prophylactic measure. The oral use of the sulfonamide was begun immediately on admission of the patient to the hospital, although there was no evidence of infection. Of these 56 eyes, 6, or 10.7 percent, subsequently developed a purulent endophthalmitis. In five of these six cases, use of the drug was begun within 24 hours after injury; in the other, 40 hours after injury.

One hundred sixteen patients received no such "prophylaxis" against infection. Twenty of these, or 17.2 percent, subsequently developed a purulent endophthalmitis. These figures do not demonstrate that any marked benefit is obtained

from the routine oral use of a sulfonamide in every case of penetrating ocular injury, the observed difference not being significant statistically. On the other hand, modern concepts of infection lead to the supposition that, in a given instance, the occurrence of infection depends on the balance between the resistance of the

TABLE 13

INFLUENCE OF DAMAGE TO THE LENS AND THE ROLE OF PROPHYLACTIC SULFONAMIDES IN THE DEVELOPMENT OF INFECTION

host and the number and virulence of the invading organisms. In a situation where these opposing forces are closely balanced, the use of any chemotherapeutic agent may well decide the outcome. The data given imply no argument against the prophylactic use of sulfonamides, and the routine use of chemotherapeutic agents, both in prophylaxis and as therapy, will, in all probability, save at least a small number of eyes which otherwise would be lost.

It has been mentioned that postoperative uveitis may be occasionally related to infection. It is therefore of interest to learn if the use of a sulfonamide influences the incidence of uveitis. Table 14 shows that after the exclusion of those cases diagnosed as purulent intraocular infection, the "prophylactic use of the sulfonamides did not influence the occurrence of posttraumatic uveitis.

TABLE 14

THE ROLE OF PROPHYLACTIC SULFONAMIDES IN THE DEVELOPMENT OF UVEITIS*

Prophylaxis	Posttraumatic uveitis	
	No.	Percent
Sulfathiazole or sulfadiazine, 50 cases	9	18
No sulfonamide, 96 cases	17	17.7

* Instances of purulent endophthalmitis excluded.

Recapitulation: The incidence of purulent intraocular infection in this series of penetrating ocular injuries was 15 percent. The incidence of infection was four times greater in those eyes which had sustained damages to the lens than among those in which the lens was uninjured. The chances of the development of an infection following a penetrating injury is not definitely reduced by the oral use of "prophylactic" sulfonamides. The outlook for recovery of an infected eye is very poor, and is only occasionally improved by the oral use of sulfonamides.

(9) *Sympathetic ophthalmia*. There were 3 instances of sympathetic ophthalmia among the 172 cases herein reported. Thirteen eyes in this series were enucleated within 14 days after injury, and could hardly be expected to have developed sympathetic ophthalmia in this short interval. Therefore, the incidence of this disease among eyes retained long enough for its development is 3 out of 159, or 1.9 percent. If the 56 cases which were

discarded as incomplete or inadequately followed, and in which there was no evidence of sympathetic ophthalmia when last seen, are included, the incidence of sympathetic ophthalmia is 3 in 215, or 1.4 percent. This approximate figure 1.4 percent probably represents very closely the true incidence in this series, and is similar to that reported by other authors, according to a review by Woods* in 1936. The three instances of sympathetic ophthalmia are summarized below.

The first was in a white girl, aged 7 years, who sustained a small perforating corneal wound near the limbus, with prolapse of iris, and without evidence of injury to the lens. After repair with iridectomy and a conjunctival flap, the eye recovered uneventfully and, two weeks after injury was free of signs of intraocular inflammation and apparently healed. During the fourth week, a bilateral uveitis developed, characteristic of sympathetic ophthalmia. The injured eye was promptly removed, and the sympathizing eye quieted down and returned to normal. Microscopic examination of the sympathicogenic eye confirmed the clinical diagnosis.

The second patient was a white boy, aged 14 years, who sustained a corneal laceration at the limbus, with prolapse of iris, the lens apparently remaining uninjured. Iridectomy was performed, and a conjunctival flap drawn over the wound. A good recovery appeared to be under way, but, on the third day, a severe spontaneous intraocular hemorrhage occurred. The hemorrhage proceeded to organize, a secondary glaucoma developed, and blood staining of the cornea took place. An unsuccessful attempt was made to remove the blood from the anterior chamber. After this, the eye began quietly to go

* Woods, A. C. *Sympathetic ophthalmia*. Part I. *Amer. Jour. Ophth.*, 1936, v. 19, pp. 9-15.

into phthisis. Three months after injury, the uninjured eye developed a mild uveitis. The cornea of the injured eye was by this time opaque. The injured eye was removed, and the diagnosis of sympathetic ophthalmia confirmed by microscopic examination. The sympathizing eye quieted down and has remained normal. This patient was known to have a strong bleeding tendency which nearly cost him his life on two occasions, when subjected to tonsillectomy and appendectomy.

The third case was unproved. A Negro boy, aged 15 years, received a small penetrating injury of the cornea and traumatic cataract. The corneal wound healed spontaneously, without prolapse of iris. Eighteen days after injury, iridectomy and lavage of the cataract were performed. Following this operation a uveitis set in, diagnosed (on the basis of an abnormal skin reaction to beef-lens protein injected intracutaneously) as iritis phaco-anaphylatica. Under desensitization treatment with lens protein and staphylococcus toxin* the injured eye quieted down and two months after injury or five weeks after operation was free of signs of intraocular inflammation. During the third month pain set in in both eyes, and when the patient returned for examination a severe bilateral uveitis had developed, clinically characteristic of sympathetic ophthalmia. Treatment was by means of artificial fever induced by 10 intravenous injections of killed typhoid bacilli. Both eyes gradually recovered without further complication. The injured, aphakic eye finally achieved corrected visual acuity of 20/40, and the opposite eye, of 20/20.

There are several points of interest in regard to the cases of sympathetic oph-

thalmia in this series. In the first case, the injured eye was healing itself without the slightest clinical trace of untoward reaction; two weeks after injury it had every appearance of a perfect result. Obviously, uneventful healing does not exclude the danger of the later development of sympathetic ophthalmia. The second patient received intensive treatment with sulfadiazine for the first 6 days after injury, and then, after a lapse of 4 days, for 11 days more. Satisfactory blood levels of the drug were obtained. In one case, therefore, considerable treatment with sulfadiazine did not prevent the later development of sympathetic ophthalmia.

Recapitulation: Sympathetic ophthalmia is proved to have occurred in 2 of the 159 cases of perforating ocular injuries in which enucleation was delayed long enough for the disease to develop, and almost certainly was present in a third, an incidence of 1.9 percent. Prompt removal of the sympathicogenic eye in two cases was followed by recovery of the sympathizing eye. In the third case, in a Negro youth, both eyes recovered.

(10) *Intraocular foreign body.* No attempt is made in this report to study the diverse problems of the intraocular foreign body. The 25 instances of this complication are included here merely to serve as a basis for estimating the influence of an intraocular foreign body on the chances for recovery from a perforating ocular injury.

In this series, of the 25 eyes with intraocular foreign bodies, 5, or 20 percent, recovered visual acuity of 20/100 or better, and 11, or 44 percent, lost all vision. On the basis of this small number, it would appear that the presence of a foreign body has an unfavorable influence on the chances for recovery.

The causes of failure among these 25 eyes are as follows: In 14 instances, the intraocular foreign bodies were success-

* Burky, E. L., and Henton, H. C. Staphylococcus toxin combined with lens extract as a desensitizing agent in individuals with a cutaneous sensitivity to lens extract. Amer. Jour. Ophth., 1936, v. 19, pp. 782-785.

fully removed; 3 of these eyes recovered visual acuity of 20/100 or better. The causes of reduction of vision in the remaining 11 (or the findings after enucleation) are intraocular infection (3 cases), nonspecific uveitis (4 cases), capsular remains (2 cases), phthisis bulbi (1 case), and uncertain (1 case).

In 11 instances, the intraocular foreign bodies were not removed. Two of these eyes recovered visual acuity of 20/100 or better. In the nine cases which did not recover useful vision, nonspecific uveitis was responsible for failure in three instances, major intraocular hemorrhage in four, infection in one, and phthisis bulbi in one. In five of these eyes, the presence of the intraocular foreign body was not diagnosed clinically and was found only on histologic section. Two of the foreign bodies were cilia.

Recapitulation: Intraocular foreign bodies appear to have an unfavorable influence on the chances for recovery from perforating ocular injuries. The incidence of posttraumatic uveitis is high among these cases, but here the evidence for a cause-and-effect relationship is unsatisfactory.

THE MANAGEMENT OF PERFORATING OCULAR INJURIES

From the foregoing study, what information is there that may be useful in improving the outlook for recovery from perforating ocular injuries?

The most important decision to be made in the management of a perforating ocular injury is whether to proceed with an attempt at repair, or whether to perform enucleation immediately. This decision will be based largely upon an estimation of the statistical chances that treatment will result in recovery in the case under consideration.

If the estimation of the chances for recovery could be brought to perfect ac-

curacy then the ideal goal of saving every possible injured eye with a maximum of efficiency would be achieved. It is fitting, therefore, to marshal the information made available in the earlier parts of this report, and to sort the various situations and complications of perforating ocular injuries into two classes: those that are reliable as prognostic signs, and those that are unreliable.

All the prognostic signs are on the negative side. No departure from the normal after traumatism is favorable. What must be determined is which abnormalities are usually reparable and which others are usually not.

The following points have been found to have a reasonably consistent adverse influence on recovery from perforating ocular injuries: (1) Injuries by blunt objects, including bullets. Injuries by very sharp instruments are much more likely to heal satisfactorily. (2) Double perforation of the globe; these may often be diagnosed by roentgenologic demonstration of the foreign body in the orbit. (3) Severe degrees of prolapse of intraocular contents; prolapse of combinations of vitreous, retina, choroid, and lens are almost always associated with irreparable disorganization. (4) Severe degrees of intraocular hemorrhage. The value of this sign is sometimes limited, since it is often impossible to distinguish between a small intraocular hemorrhage and a large one in an eye disrupted by injury. Careful transillumination may help to make the distinction. (5) Intraocular infection. Any degree of infection is seldom handled satisfactorily, even with the help of the sulfonamides, although newer chemotherapeutic agents may alter this situation. (6) The presence of an intraocular foreign body probably reduces the chances for satisfactory recovery.

The following signs, in contrast to the above, are unreliable as prognostic

guides: (1) The location of the laceration. (2) The length of the laceration; by itself this sign is of little importance, however it may imply the occurrence of two unfavorable complications—severe hemorrhage and severe prolapse. (3) Traumatic cataract in itself is not a reliable prognostic guide, although it may favor the occurrence of infection and of uveitis. (4) Small degrees of prolapse, especially prolapse of iris. (5) Minor degrees of hemorrhage.

It must be pointed out that these remarks concerning the role of the location of the injury are not meant to dispute the familiar statistical evidence that sympathetic ophthalmia occurs more frequently in wounds of the ciliary body. What is meant is that when confronted by a fresh ocular injury, the surgeon's estimate of the chances for uneventful healing should be little influenced by the location of the laceration. However, later on, if healing fails to proceed satisfactorily, the presence of a wound in the ciliary body should have considerable influence in the choice of management.

A summary of the relative prognostic merits of the various complications is given in table 15. It is from such signs that the surgeon must decide whether enucleation is indicated, or whether it is worthwhile to proceed with attempts at repair.

If it is decided to proceed with attempts to repair an eye that has received a perforating injury, a choice must be made from among several possible methods of surgical attack. For the repair of corneal lacerations, there are two principal methods: The use of direct corneal sutures or of a conjunctival flap. In an effort to determine the relative merits of these and other methods of repair, the cases in this report have been analyzed in respect to the type of surgical treatment given.

The various surgical approaches in cases of corneal laceration fall into four groups: (1) No surgical interference, treatment consisting of atropine and pressure bandages; (2) simple conjunctival flap, after debridement of the wound and iridectomy; (3) corneal sutures, after debridement and iridectomy; (4) a combination of corneal sutures and conjunctival flap with debridement and iridectomy.

TABLE 15
PROGNOSTIC SIGNS IN PERFORATING
OCULAR INJURIES

Factors Almost Always Associated with Failure:	Factors with no Consistent Relation to the Final Outcome:
Injury by a blunt object	Location of the perforation
Double perforation of the globe	Length of the laceration
Intraocular infection	Prolapse of iris
Severe degrees of prolapse of intraocular contents	Injury to the lens
Severe intraocular hemorrhage	Minor intraocular hemorrhage

In the study of the relative merits of each of these four methods, the discussion applies only to corneal lacerations, penetrating injuries not involving the cornea being excluded from this part of the analysis. Moreover, all cases demonstrated to be complicated by intraocular infection were likewise excluded, since this complication introduces another variable not clearly related to the type of surgical treatment. For similar reasons, cases with retained intraocular foreign bodies were excluded. After these exclusions, there remained a series of 109 eyes having corneal or corneoscleral lacerations, not infected, without retained intraocular foreign bodies, which were treated by one of the four methods given above (table 16).

Since it is important to learn if a division according to the surgical manage-

ment results in groups that are comparable, the data as to the incidence of prolapse and of damage to the lens and the average length of the laceration are given as indices of the severity of the injury. Thus in group 1, wherein treatment consisted of atropine and pressure bandage only, the injuries were shorter, there was a less frequent incidence of prolapse, although the incidence of damage to the lens was high. Moreover, most of the

haps demonstrate that for small lacerations without prolapse nonoperative treatment is as adequate as in direct surgical repair for more serious injuries. That none of the eyes receiving nonoperative treatment required enucleation is probably a further reflection of the relatively minor nature of the injury, and there is no evident reason for attributing the superiority in this respect to the treatment.

In the remaining groups, there is a rea-

TABLE 16
INFLUENCE OF THE TYPE OF SURGICAL TREATMENT ON THE FINAL VISUAL ACUITY*

Type of Repair	Average Length mm.	Iris Prolapse percent	Lens Injury percent	Final Corrected Visual Acuity			Break-down of Wound percent
				20/100 or Better percent	Worse than 20/100 percent	Blind percent	
I No repair, 22 cases	4.0	14	59	77	23	—	—
II Corneal sutures, 21 cases	5.2	71	19	81	9.5	9.5	24
III Sutures and flap, 17 cases	7.0	88	41	65	23	12	6
Average of II and III, 38 cases	6.0	78	29	73.5	16	10.5	16
IV Flap only, 39 cases	4.8	85	38	51	28	21	13

* Corneal and corneo-scleral lacerations, excluding cases complicated by infection or by intraocular foreign bodies.

lacerations in group 1 were of 1, 2, or 3 mm. in length, the average being raised by three cases in which the laceration measured 9 mm. or over. In almost all of these there was spontaneous coaptation of the wound. That prolapsed iris was left in any instance is accounted for by the fact that the definition of iris prolapse used in this paper includes any case wherein iris tissue was present between the lips of the wound, although there may have been no actual protrusion.

Thus, the first group of cases, in which no operative treatment was undertaken, is not comparable with the other groups. The results achieved in this group per-

sonable degree of uniformity in the average amount of damage sustained. One situation helps to make the remaining groups similar and comparable. In the earlier days of the Wilmer Institute, it was the practice to repair all corneal lacerations by means of a conjunctival flap, and corneal sutures were rarely used. In the last few years, this attitude has been almost directly reversed, and nearly every eye needing repair has been treated with corneal sutures, at times supplemented by a conjunctival flap. Thus there are two groups of cases in which all random influences could operate equally, and in which the decision as to the technique

of surgical repair was influenced almost solely by the prevalent custom.

There were 39 lacerations that were repaired by a conjunctival flap, usually after iridectomy. Fifty-one percent of the eyes involved regained a corrected visual acuity of 20/100 or better, while 21 percent ended with loss of all light perception.

There were 38 cases which were repaired by the use of corneal sutures, in 17 of which a conjunctival flap was used in addition to the corneal sutures. In this group, 73.5 percent of the eyes regained a final corrected visual acuity of 20/100 or better, and 10.5 percent were blind.

The incidence of breakdown of the wound for each group is also given in table 16. Under breakdown is included delayed re-formation of the anterior chamber of over four days' duration, or loss of the anterior chamber after re-formation, as well as actual gaping of the wound with or without prolapse. The incidence of breakdown is high in those cases in which corneal sutures alone were used. Here the incidence of breakdown is increased because of a few cases in which the anterior chamber was temporarily lost on removal of the sutures. Where a conjunctival flap alone was used, the incidence of breakdown was 13 percent, and where both corneal sutures and conjunctival flap were used, the incidence of breakdown was 6 percent. While the incidence of breakdown appears to be inversely proportional to the apparent watertightness of the repair, the numbers involved are small and not significant.

The apparent advantage of corneal sutures over a simple conjunctival flap must be viewed with caution. From the statistical standpoint the observed difference in the two groups is barely significant. While the groups appear to be more or less similar, there are many possible ran-

dom influences which might not have occurred with uniform frequency in two groups of this limited size.

On the basis of the foregoing analysis there appears to be no distinct advantage of one method of repair over another, on the average, although one may be superior to the other in a particular case (see below).

With the foregoing evidence in hand regarding the importance of various complications and the relative merits of the various types of surgical repair, what generalizations can be made as guides in the treatment of perforating ocular injuries? The following suggestions, while not original, are familiar methods, with occasional modifications suggested by the analysis of these 172 cases.

In the first place, the usefulness of non-operative management should be kept constantly in mind. Table 16 demonstrates that many corneal wounds which coapt spontaneously, without prolapse, are seen to heal readily under nonoperative treatment. Where such treatment can be used, it is ideal. It should not be applied when there is any material between the lips of the wound, or any gaping of the wound, since these situations tend to increase the inflammatory reaction and the amount of scarring and may delay healing. Whenever surgical debridement of the wound is necessary, closure should be effected. It goes almost without saying that before surgery is undertaken in a perforating ocular injury most careful attention should be given to the possibility of an intraocular foreign body. Even when this complication seems unlikely, it should be investigated thoroughly in the history, in the clinical examination, and (ideally) by routine roentgenologic examination.

In proceeding with the surgical treatment of corneal or corneoscleral wounds, the first consideration is debridement of

the wound. Since there is evidence that prolapse of iris may prevent the development of infection, iridectomy should always be deferred until the time of repair of the wound and other measures of protection against infection are available. Iridectomy is the wisest method for reduction of a prolapse of iris, even though it may sometimes be tempting to try to reposit a prolapsed but otherwise intact iris. The complications to be feared from the latter course are intraocular infection and recurrence of the prolapse as the aqueous is re-formed. Besides iris tissue all other material and foreign bodies should be removed from the wound and pieces of cilia should be carefully sought.

The removal of blood clots from the anterior chamber is most desirable in view of the adverse effect of a clot which organizes instead of becoming absorbed. Moreover, during surgical repair, if fresh bleeding occurs, the wound should never be closed until the bleeding stops and the hemorrhage is evacuated.

The question of the management of the complication of a traumatic cataract arises at this point. Since traumatic cataract often favors the development of more serious complications, and at best requires a second operative procedure, it is wise to remove the cataract by lavage or piece by piece at the time of repair of the injury, *provided* that the cataract is sufficiently developed so that it is susceptible of reasonably complete removal, and provided that removal can be accomplished without serious risk of aggravating hemorrhage or prolapse. Unless these provisions are met, treatment of the traumatic cataract should be deferred for several months.

For closure of a corneal or corneoscleral wound, the choice of corneal sutures versus a conjunctival flap will be based on the sum and average of the fol-

lowing factors: First, the degree of gaping of the wound. A conjunctival flap does not appear to be reasonable treatment if the wound is gaping under the flap. Healing will occur with a smaller scar if the wound edges are approximated with sutures. Secondly, the raggedness of the wound and the degree of maceration of tissue. If the wound edges are macerated or very much softened by early reaction, sutures are impractical, and the defect heals best with a conjunctival flap over it. Third, the degree of damage to the lens. If the lens is intact, it may be considered that the placing of corneal sutures affords an unnecessary hazard in operative traumatic cataract. Fourth, the location of the laceration. If a conjunctival flap should adhere to a central corneal wound, the resulting leukoma would be greater than if the wound were closed with sutures; the sutures need not be placed directly in the course of the visual axis, but on one or both sides of it. Fifth, the unruliness of the patient. Where poor postoperative coöperation is expected, the tighter the closure of the wound the better. On the other hand, in children, removal of corneal sutures may necessitate a second anesthesia, which is avoided by the use of a conjunctival flap with absorbable sutures, or with silk sutures which quickly cut their way out spontaneously.

When corneal sutures are used, the simplest sutures are probably the best. The cornea is usually sufficiently tough so that simple sutures give adequate closure without danger of tearing out. Simple single sutures give the least amount of scarring. They should not penetrate Descemet's membrane, but should pass in mid-stroma, to reduce the chances of temporary fistula formation on removal. Silk corneal sutures can be removed after 9 to 12 days. After closure of the wound.

the injection of air or saline in the anterior chamber is sometimes useful to prevent the formation of anterior synechiae. The use of air is preferable, since it is retained more readily. All corneal lacerations should be dressed with a firm pressure bandage.

Scleral wounds are closed if necessary with simple direct silk sutures which may be buried or may be tied outside the conjunctiva. Nonchromatized absorbable sutures are, perhaps, preferable. Such injuries are relatively rare. Theoretically they should be associated with an increased incidence of retinal separation; for this reason, the use of a few diathermy punctures about the wound may be advisable.

Nonoperative procedures are similar to those used in conjunction with other phases of ophthalmic surgery. Atropine is almost always indicated postoperatively. The "prophylactic" use of sulfathiazol or sulfadiazine in all cases is probably wise, since about one in every seven eyes with a perforating injury is lost through infection. Although statistical proof of the value of this procedure is lacking, there is reason to believe that in some cases it may be of value. The good results from artificially induced fever for the treatment of postoperative iritis is well recognized. This procedure, moreover, is occasionally used as a "prophylactic" measure before the development of the uveitis. Since the relationship between injury to the lens and post-traumatic uveitis is so striking, the prophylactic use of artificial-fever therapy

should be reserved for cases complicated by traumatic cataract.

When uveitis develops in the presence of a traumatic cataract, the possibility of uveitis phaco-anaphylactica should be investigated, and can be demonstrated by an abnormal skin reaction on the intra-dermal injection of lens protein. If this diagnosis is established, treatment with lens protein and staphylococcus toxin may lead to recovery.

SUMMARY

In an analysis of 172 cases of perforating ocular injuries, the following factors are seen to have a reasonably consistent unfavorable influence on the chances for recovery: (1) Injuries by blunt objects; (2) double perforation of the globe; (3) severe degrees of prolapse of intraocular contents; (4) severe intraocular hemorrhage; and (5) intraocular infection. On the other hand, recovery is not consistently influenced by (1) the length of the laceration; (2) the location of the laceration; (3) injury to the lens; (4) prolapse of iris, and (5) minor degrees of hemorrhage. The interrelationship of some of these complications is discussed. The (corrected) incidence of sympathetic ophthalmia among these cases is 1.45 percent.

In the choice of methods of repair of corneal lacerations, the use of a conjunctival flap, or the use of direct corneal sutures appears to be about equally efficacious. Other features in the management of perforating ocular injuries are discussed.

TRACHOMA VIRUS AND THE MORPHOLOGY OF INCLUSION BODIES*

ARNOLD LOEWENSTEIN, M.D. (*Prague*)
Glasgow

The inclusion bodies found in trachoma may have an etiologic link with the virus that is assumed to cause the disease. Many attempts have been made to establish this view but two important difficulties stand in the way: inclusion bodies that are microscopically indistinguishable from those found in trachoma are found in other conjunctival diseases, and the virus has not been produced in culture. The bodies are found in both recent and long-standing cases of trachoma, with a frequency that increases with the care and experience of the investigator. A negative report has no value unless scrapings are examined from several areas of the fornix and both the palpebral and the bulbar conjunctiva. Much misunderstanding has arisen from the inadequate illustrations that have appeared. Even the best photomicrographs are disappointing compared with carefully executed drawings.

Towards the end of the last war I published some illustrations of the great polymorphism that may be found in these bodies (plate 2, frontispiece). Preparations made from epithelial scrapings present appearances that differ from those made from conjunctival sections. The superficial epithelial cells of the conjunctiva are probably the starting point for the infection of the deeper tissue. Consequently, great attention has been paid to them to the neglect of the deeper layers. In these superficial cells the inclusion bodies may be found sitting like a cap on the nucleus, although some may lie

free in the plasma. They may differ in size and intensity of staining. In size their elements may vary from 0.25μ to nearly 1.0μ in diameter, and a clear halo may surround them. In plate 1 the blue-stained bodies can be seen to vary in shape very considerably; "cocci," barrels, double "cocci," rings, dumb-bells and hour-glasses may be present. The whole cell may be full of these bodies and the wall may burst, thus liberating them. Such open cells may be seen in both scrapings and in sections. They are probably not due to artifact but actually occur in life. It may be that these small elementary bodies are the actual virus elements which are distinguishable from the larger initial bodies.*

In two cases of traumatic conjunctivitis I suspected infection with trachoma. Epithelial smears were taken daily from the third day after the accidents. The findings were negative until the sixth day when intracellular elementary bodies and all shapes of initial bodies were found in many epithelial cells. These elements were present in increasing number on the ninth day and the first typical inclusion bodies were found on the fifteenth. They were few in number and stained lightly. Both these patients later developed classical trachoma, with many typical inclusion bodies. The disease finally subsided after some months of energetic mechanical treatment. The impression gained is that the elementary bodies intrude upon the cell from without, develop into the initial body, and by the multiplication of the latter the characteristic inclusion

* From the Tennent Institute of Ophthalmology, University of Glasgow (Prof. W. J. B. Riddell).

* The cells shown in the illustrations were drawn for me by Mr. Zovetti.

bodies are formed. If this speculation is correct it follows that both initial and elementary bodies may be found in the cells without any inclusion bodies. The aforementioned cases would give support to this view.

Trachoma is not a disease restricted to the epithelium. The principal pathologic reaction is seen in the submucosa, where large masses of lymphocytes, plasma cells, and fibroblasts infiltrate the tissues. Deep scarring may shorten the conjunctival fornix, and the infiltrated tarsal plate may be distorted. These well-known clinical facts suggest that the infective process penetrates deeply into the tissues. In a report to the International Ophthalmological Congress in Egypt, Wilson (1937) stated that "true inclusion bodies, which one finds in the epithelial cells of the conjunctiva, are not found within the trachomatous follicle." On the other hand, subepithelial caps of extremely small Giemsa-staining elementary bodies (*rickettsia*) were reported by Cuénod and Nataf (1935, 1936, and 1937). They have been found in smears from the contents of trachoma follicles. Cuénod stated that they were "not common mast-cells, but cells filled with parasites."

I prepared paraffin sections from the conjunctiva of the fornix derived from 23 cases of trachoma. Moreover, I was able to study four excised trachomatous tarsal plates histologically. For two of them I am indebted to MacCallan. I acknowledge gratefully his kindness. The sections were stained with hematoxylin and eosin, van Gieson, Unna-Pappenheim, and Giemsa stains. In a certain number of sections both Victoria blue and polychrome methylene-blue stains were used. In areas where typical inclusion bodies were found in the superficial layers the underlying tissue was carefully examined. The inclusion bodies were situated in nests (figs. 4a, 4b) in the

superficial epithelial layers, mostly in groups of 30 to 50, surrounded by epithelium free from inclusion bodies. They differed from those found in the smear preparations in that most of them lie within delicate cystlike compartments. The "initial bodies" did not vary in shape to the same extent as in the smear preparations. The elementary and initial bodies could be distinguished only by the size of the granules. The smaller compartments contained 2 to 5 units whilst the largest might contain 30 to 40. The number appeared to be conditioned by the size of the balloonlike spaces. This cystlike appearance can be seen most easily with Giemsa staining, being but rarely visible when hematoxylin and eosin were used.

No such cystlike compartments were found in the deeper epithelial layers. But inclusion bodies may be present as deep as the basal epithelial cells. These corpuscles are freely imbedded in the epithelial layer, and the halo seen in the superficial layers or that of the smear preparations is absent. This halo is assumed to be a jellylike mucous substance (van Rooyen and Rhodes, 1940). The nucleus of the invaded cell may be displaced by the bodies; sometimes the whole plasma may be occupied by inclusions and no nucleus can be seen. Polymorphonuclear leucocytes migrating through the epithelium did not contain any inclusion bodies or Giemsa-staining granules (figs. 4c-8d).

In all advanced cases the submucosa contains numerous follicles, many of them forming densely infiltrated areas. These follicles consist of lymphocytes, plasma cells, leucocytes, and fibroblasts. Basophilic mast cells were found frequently in the less densely infiltrated reticulum (plate 5). Some of these cells displayed a typical wheel-shaped nucleus, others were reticulum cells with large,

pale nuclei and very little chromatin. The cells of fibroblast (histiocytes) type were frequently packed with blue and purple granules. Sometimes granules of both colors were found in the same cell. These granules may also lie in heaps free in the tissue and small groups may be seen without any relation to cells. Serial sections stained alternatively with Giemsa and hematoxylin were examined, and no basophil granules were found in the latter. Under high magnification ($\times 1,350$) reticulum cells full of delicate elements showing both metachromatic and blue staining were seen frequently in the same field. Others showed a cytoplasm full of corpuscles with considerable variation in size (fig. 8c).

Sections prepared from the tarsal plate that had been excised from long-standing cases of trachoma were examined by the aforescribed methods. The whole tarsal plate was filled more or less with reticulum cells choked with dark blue or purple elements stained with Giemsa; thin fibroblasts were seen to be filled with blue or purplish granules; and many round elements were seen free in the tissues. Sometimes chains were formed like small streptococci. Similar appearances were present in the submucosa of the bulbar conjunctiva (figs. 9-10).

Slides were prepared from two cases

of follicular catarrh, and from acute and chronic conjunctivitis. No epithelial inclusions were found from scrapings in any of these, but basophilic mast cells were frequent in the sections of follicular catarrh. The granules of these cells could not be distinguished from those occurring in the trachoma cases.

DISCUSSION

The morphologic appearance of the various types of epithelial inclusions strongly suggest that they are the virus elements. The differences between the appearances in scrapings and in sections may be due to the technique employed. I cannot explain the reason of this difference nor why the colonies in the deeper epithelial cell rows do not show the cyst-like appearance found in the superficial layers. The nestlike localization of the inclusion bodies indicates the need for most exhaustive examination of the sections. It often happened that a negative section was found to be positive after repeated scrutiny. The difficulties increase when a search is made for intraplasmatic single elements in the deeper tissues which may be quite obvious in epithelial scrapings. Only the colonies can be recognized in sections without difficulties.

I imagine that the series of events is

somewhat as follows: The virus invades the superficial epithelial cells of the conjunctiva where its elements grow into colonies, the inclusion bodies. The virus elements are carried into the deeper epithelial layers by the lymph stream and

present from the earliest stage (Birch-Hirschfeld, 1938), may act as phagocytes by reabsorbing the virus, although unable to destroy it. The subsequent development of fibrous tissue thus leads to the deep storage of infective material.

Fig. 4a

reach the subepithelial tissue. At that level a follicular growth is produced, analogous to that found in lymphatic leukemic tumors. The interaction between virus and tissue conditions the production of follicles and the predominantly lymphocytic growth. The fibroblasts, which are

This may account for the frequent relapses in cases of long-standing trachoma. It is another reason justifying the excision of the tarsal plate in such cases.

Reticulum cells with round granules staining with Giemsa were observed in two cases of follicular catarrh. Certain

forms of this condition are infectious and may be due to a virus, although visible epithelial inclusion bodies have not been seen so far. I have seen similar reticulum cells filled with Giemsa blue granules in pemphigus of the conjunctiva, although no inclusion bodies were found in conjunctival scrapings. The virus nature of this conjunctival disease was discussed by Gallardo and Hardy (1943). Molluscum contagiosum is considered to be a virus disease also (Lip-schütz, 1913), and follicles of a similar type to those of trachoma are found in this disease.

The whole problem of the nature of inclusion bodies in these conditions calls for much further investigation. The present observations remain inconclusive. There is not more than a probability that both the intraplasmatic Giemsa-staining elements in the reticulum cells and the extracellular ones are the virus itself.

SUMMARY

In advanced trachoma the follicles consist of lymphocytes, plasma cells, fibroblasts, and macrophages [cytrophages (Marchand)]. The last may be very large and contain half digested cells, remains of erythrocytes, splinters of nuclei, but no granules suggesting inclusion bodies. The cell remnants stain with both Giemsa and hematoxylin. The caps reported by Cuénod in the cells of the follicles were not found in any of the 23 cases of advanced trachoma which form the basis of this histologic investigation. Metachromatic granules, rather indistinct and cloudy, were found in plasma

cells having a typical wheel-shaped nucleus.

The appearance of the inclusion bodies differs in scrapings and in sections. In the scrapings they show considerable polymorphy, and individual elementary and initial bodies may be found alone in the cells.

In sections, encapsulated inclusion bodies with many Giemsa-staining elements are found in the superficial epithelial layers. In the middle layers the encapsulated inclusions tended to be smaller, with fewer elements. Groups of elements lying free in the epithelial plasma without either capsule or halo may be the virus itself as well. No encapsulated colonies were seen in the deepest layers of the epithelium. In the middle and deepest epithelial layers single reticulum cells full of metachromatic granules were present.

In the subepithelial tissues, reticulum cells of fibroblast character were filled with blue and purple granules. The size varied, but many were equally sized and equal to that of the intraepithelial elements. Granules were free in the tissues, some single and others in colonies.

The diseased tarsus was found to be full of reticulum cells of fibroblast character with blue and purplish elements in large numbers, both inside and outside the cells. Similar granules were not found either in the lymphocytes or in the plasma cells.

It is possible that both the intraplasmatic Giemsa-staining elements in the reticulum cells and the extracellular elements are the virus itself.

IODIDE THERAPY FOR SENILE MACULAR DEGENERATION*

R. G. LAIRD, M.D.

Grand Rapids, Michigan

In 1885 Haab¹ described the condition which we know as senile macular degeneration. De Schweinitz² pronounced this a loose term and classified it as a lesion or lesions which arise in senescence, at 50 years of age and older. His description of senile macular degeneration is a masterpiece:

In the very early stage the macular area may exhibit features which differ only slightly from those common to elderly people; a color darker than normal, a faintly muddy hue or a delicate mottling. Later, close focusing reveals a number of brownish black granules interspersed with others which are light colored. Occasionally there are white glistening dots which are often mistaken for Gunn's dots, with which they have nothing in common. In the macula are small yellowish white spots, interspersed with pigment dots and minute hemorrhages, or irregular shallow erosions, which may go on to atrophy of the elements and slight pigment heaping. The descriptive title, moth eaten macula has been applied. While it is true that in these early stages the visual disturbance is often out of all proportion to the inconspicuous pathological changes, it is also true that sometimes at this period, although sight is indistinct the vision is normal for the usual tests. It is generally maintained that treatment is unavailing. The prognosis of this condition is favorable in that it does not produce total blindness, but it is not influenced by any form of treatment.

Duke-Elder³ agrees that treatment is extremely unsatisfactory. He believes the condition to be due essentially to proc-

esses outside medical control. Moreover, in all such cases we are dealing with tissues of low vitality which are in no condition to respond to therapeutic or stimulatory measures.

This prognosis leaves a patient with but little hope. It offers a sad outlook for the remainder of his allotted days, at the time when he is frequently limited in physical ability and needs his vision desperately to live with any degree of happiness. It is the purpose of this paper to hold out some hope to this type of patient.

Volumes have been written on sclerosis of the retina, while relatively little has appeared in print concerning sclerosis of the choroid. This discrepancy is due to the fact that the retina may usually be examined with the ophthalmoscope but the choroid only occasionally. H. Friedenwald,⁴ J. S. Friedenwald,⁵ de Schweinitz,² and H. Wagener⁶ (among American authors) have contributed much to our knowledge of retinal sclerosis. It is believed that retinal sclerosis plays a negligible part in senile macular degeneration.

Duke-Elder,³ in defining senile macular degeneration, writes that it is due to sclerosis and obliteration of the choriocapillaris. B. Rones⁷ also is of this opinion. He states: "Obliteration of the choriocapillaris is of primary importance in producing the retinal changes. The pigment epithelium is an early sufferer from

* Candidate's thesis accepted for membership in the American Ophthalmological Society, June, 1944.

this diminished circulation and its changes are partly of a proliferative and partly of a degenerative nature." Kondo⁸ considered sclerosis of the choroidal vessels to be of cardinal importance in macular degeneration. The majority of writers agree with this explanation as the cause of senile macular degeneration.

J. S. Friedenwald⁹ states that "Atheroma of the choroidal vessels does not manifest itself directly in any ophthalmoscopically visible change. This statement can be made with some assurance because the great majority of persons over 65 years of age have histologically demonstrable atheromatous changes in the choroidal vessels while only a small proportion exhibit these atrophic changes in the choroidal tissues which are attributed by clinicians to choroidal sclerosis. These atrophic lesions occur preëminently in the macular and peripapillary regions and in the extreme periphery of the fundus." Cohen⁹ states, "Arteriosclerosis may exist in any of the intraocular vessels without clinical evidence of its presence elsewhere in the body." Friedenwald further states: "Until more definite evidence is available to show these atrophic lesions are directly connected with disease of the blood vessels, it seems best to classify them along with peripheral cystic degeneration of the retina and the pigment atrophy of the pupillary margin of the iris as senile rather than arteriosclerotic." That many authors are in agreement with this opinion is unquestioned.

A. Sorsby¹⁰ and P. Waardenburg¹¹ have presented proof that some cases may be abiotrophic.

The pathologic changes have been investigated by Nagel,¹² Harms,¹³ C. Behr,¹⁴ J. S. Friedenwald,⁵ and Rones.⁷ Nagel was chiefly concerned with the yellowish white spots found about the posterior pole of the globe. He concluded that these spots were granules of calcium

carbonate in drusenlike thickenings located in the lamina elastica. Pigment granules were not found in such thickenings but always upon the surface of the smaller and entirely displaced only by the larger thickenings. He thought the impairment of vision was due to pressure of these thickenings upon the external layers of the retina. He does not mention the condition of the blood vessels.

Harms found the lesions confined to the pigment epithelium and neuroepithelial layer of the retina, with the choroid not involved. C. Behr confirmed the findings of Harms. He advanced the suggestion that senile macular disease should be regarded as a special type of hereditary degeneration, depending upon a congenital predisposition to premature death of the macular retinal neurons.

Friedenwald reports "In these cases the essential lesion seems to be in the choroid, and while it may occur at any point in the fundus, the point of election is at the macula. The choroidal capillaries here become obliterated and show hyalin degeneration. There is both atrophy and proliferation of the overlying retinal pigment epithelium, with the formation of many colloid excrescences on Bruch's membrane and some scattering and heaping up of pigment. The deeper layers of the retina which are dependent upon the choroidal capillaries for their nutrition become atrophied and disorganized; indeed, the atrophy may extend throughout the whole macular region."

Rones states:

Histologically it is evident in these cases that obliteration of the choriocapillaris is of primary importance in producing the retinal changes. The role played by the choriocapillaris in the nutrition of the retina is of the utmost importance, and consequently, any great impairment of its function must necessarily exercise a deleterious influence upon its dependent tissues. The pigment epithelium is an early sufferer from this diminished circulation, and its changes are partly of a proliferative and partly

of a degenerative nature. Many of the cells increase considerably in size, so that the layer loses its regular appearance. Though there is evidence of cellular division, many cells show signs of degeneration, with pale vacuolated nuclei. There is also considerable variation in the pigment content of the cells and many of them lose all of their pigment. The pigment granules do not have their normal rod form, but become small and round, and with the destruction of the cells are scattered over the basal membrane. In elderly people the choriocapillaris exhibits many caliber variations, some vessels being almost occluded while others exhibit compensatory dilatation. The arteries are also seen to vary in their caliber and their walls show definite thickening. Where an artery is found to be occluded, the entire zone of choriocapillaris which it feeds is found to be atrophied, while an adjacent zone may appear quite normal. It follows that atrophy of the capillary layer occurs in a very patchy manner.

In the earlier stages of senile macular degeneration the patient complains of a slight blurring of vision which persists after refraction. If the macula is carefully examined usually a slight disturbance of pigment or a paleness will be detected which may vary only slightly from the normal. Sclerosis of the retinal vessels may or may not be present at this time. In the cases reported here sclerosis was present in every instance. Later in the progress of the disease there is a minute dispersal or heaping of pigment which manifests itself as small light or small dark dots. Retinal sclerosis is nearly always present at this stage. Still later these pigment changes are conspicuous and in the end stages the macula is almost entirely destroyed, only a few small clumps of retinal cells remaining in this area. In any stage of these changes a macular hemorrhage may complicate the ophthalmoscopic picture and hasten the progress of destruction.

The vision may be impaired early in the disease when the fundus examination reveals a questionable variation from the normal fovea and when sclerosis of the retinal vessels is not marked. In certain

cases the vision may not be impaired until the macular changes are easily discernible. The impairment of vision may be out of all proportion to the ophthalmoscopic picture and again the vision may be surprisingly good where the damage to the fovea is extensive. In the latter instance the vision is nearly always diminished. In the later stages the vision is invariably poor.

The foveal changes can usually be seen in senile macular degeneration, so perimetry is not often employed. Traquair¹⁵ states that even when minute retinal lesions are detected, the field defects often indicate a much larger area of functionally altered retina than is indicated by the ophthalmoscopic findings. In some instances, relative blue-yellow blindness may be present. At times the scotoma may be central and less than two degrees in diameter, whereas in other cases the field defects suggest homonymous or bitemporal hemianopic or quadrant-shaped scotomata. This may be the case without the presence of visible corresponding retinal lesions, for it is by no means always possible to correlate the field defects with the visible foveal changes. This discrepancy of findings is due to the patchy atrophy of the choriocapillaris described by Rones.

Senile macular degeneration is encountered in persons of middle age or beyond, who usually are in reasonably good health and actively engaged in some occupation. It is less often encountered in individuals with poor health. They frequently have a slight increase in systolic blood pressure and in many instances hypertension of a mild or severe degree may be present. These patients are frequently of a nervous temperament and some are apprehensive concerning the prognosis of their vision.

Iodine was first discovered by Bernard Courtois, a Parisian chemist, in 1811.

Since that time it has had a varied and interesting history. It has been prescribed for most of the ills of humanity at one time or another. Volumes have been written upon its various actions but despite this its hormone and alterative mysteries are not completely solved. There is considerable diversity of opinion among clinicians and experimental investigators with respect to its influence upon the circulation and the vascular system.

In 1914 Schwalbe¹⁰ sent questionnaires to practitioners and clinicians. Their answers revealed an evident lack of agreement as to the action of iodide in arteriosclerosis, as well as to the favorable alterations and functional amelioration it induces, and finally its value as a symptomatic agent against subjective manifestations. In a review published in 1933, Liebig¹⁷ was unable to report any recent observations from this angle.

Experimental investigations of the effect of iodine on the circulation have embraced mainly: (1) Its effect upon vascular caliber; (2) effect upon pathologic alterations of the vascular walls; (3) effect upon blood mass; and (4) effect upon viscosity of blood plasma.

In 1927, Guggenheimer and Fisher,¹⁸ in experiments with animals, found that iodine produced vasodilation and fall in blood pressure, the best results being obtained with a dilution of 1:1-5 million. Freund and König¹⁹ in 1928; Mancke in 1930;²⁰ Osterman²¹ in 1930; and Barkan and Prikk²² in the same year could not obtain these results with similar experimentation. Barkan and Prikk stated: "With regard to the circulation, the action of iodide has not as yet been clarified by experiment. In this and other respects it still remains a pharmacological problem."

Murata and Kataoka in 1917;²³ Liebig in 1931; Turner in 1933;²⁴ and Page and

Bernhard²⁵ in 1935, found that iodine in large doses prevented the occurrence of atheromatous vascular changes in rabbits fed with cholesterol. Attention was directed to the importance of the thyroid gland by Shapiro in 1927.²⁶ Turner and Khayat²⁷ in 1933, found that the presence of the thyroid gland is a prerequisite for the manifestation of this action of iodine. Murata and Kataoka determined that the presence of thyroxin was a factor in retarding these changes. This was corroborated by Turner in 1933, and by Friedland²⁸ in the same year.

Handousky²⁹ (1938) experimented by feeding dogs large amounts of pure vitamin D. No changes could be found in the arteries of the normal animal. Following removal of the thyroid and parathyroid severe sclerotic changes in the aorta as well as the pathologic picture of a nephrosclerosis ensued. If thyroxin was administered to the animals after the operation, simultaneously with the vitamin these aortal changes did not appear. Handousky concluded that a hyperfunction of the thyroid favors the occurrence of arteriolonecrosis and inhibits arteriosclerosis; a hypofunction inhibits arteriolosclerosis and favors the appearance of arteriosclerosis.

Kraus³⁰ (1935) found that 4-percent abrodil produced a maximal dilatation of intact vessels in the ear of a rabbit, although he tested concentrations as high as 40 percent. An interesting item is reported by Saglitzer, Demel, and colleagues³¹ (1930-34). They injected urocelectan or abrodil for the purpose of arteriography in patients with severe arteriosclerotic disturbances of the extremities. Some of these patients were so improved by a single injection that they were able to resume their former occupations for periods up to three years. Nils Alwall³² (1939) gives a very excellent

bibliography in a résumé of the iodide problem and adds the results of his experiments on plasma viscosity. He concludes that iodides have little or no effect on the plasma viscosity and suggests that iodides may exert their influence upon the pathologic changes of the vascular wall.

Many ophthalmologists are prescribing iodides in various forms but only a few have recorded their results in the literature. Pflüger³³ used iodine trichloride solution 1:3,000 to 1:2,000 for cases of acute infection and sodium iodide with sodium chloride for chronic cases. His method was to inject 2 to 4 gm. subconjunctivally, combined with paracentesis of the anterior chamber. He obtained spectacular results in various intraocular infections, progressive myopia, detachment of the retina, and central retinochoroiditis. Gallemaerts³⁴ injected postassium-iodide solutions subconjunctivally. Sourdille³⁵ and Panas³⁶ treated several types of choroiditis with pure iodine and solutions of potassium iodide; one injection every two to three days in conjunction with constant current, and reported excellent results in various conditions, and improvement in choroiditis macularis. Naegeli³⁷ studied the effect of subconjunctival employment of iodipin, recommended as a substitute for the iodides, on the eye of the rabbit. He found it well tolerated, although subcutaneous injections of slightly larger doses deposited approximately the same amounts of iodine in the various tissues of the eye. He considered the iodine to act as a very energetic agent of resorption, especially of pathologic substances.

Schicle³⁸ presents a comprehensive review of the history of the injections of sodium-iodide solutions. His preferred method was to inject 1 c.c. of 1:1,000 solution of sodium iodide to which three

drops of 1-percent acoin (a local anesthetic) had been added.

Jensen³⁹ and Cowan and Jordan⁴⁰ inject Pregl's solution subconjunctivally for various ocular affections with good results.

E. Metzger⁴¹ preferred 10 c.c. of 10-percent solution of sodium iodide given intravenously, and found that this was tolerated by patients who were sensitive to other preparations of iodide. He recommended daily injections in severe cases.

In the series of cases, reported by the present writer, oral administration was composed of protiodide of mercury in 0.125- to 0.25-gr. tablets thrice daily. If it was thought that this form of iodide would not be tolerated, either Lugol's solution or saturated potassium iodide was given. The dosage of the iodide solutions was gauged by the individual tolerances, and in no instance was a dosage of 20 drops thrice daily exceeded. The usual variations of tolerances were encountered. Some patients were able to take fairly large doses while others could not endure iodide in any form without severe gastric discomfort or the appearance of skin rash. Little difference was noted in the end results brought about by these three types of iodides. More than one half of the cases reported in this series improved on oral administration alone. This percentage would undoubtedly have been larger had all the cases been tried on this method but, for various reasons, some were given iodides by injection from the beginning of their treatment. Administration was continued as long as the vision improved and then was given on alternate months. It was discovered that in certain cases the vision, in a few months, would decrease if iodides were entirely discontinued.

Four different preparations of iodide for subcutaneous injection were admin-

Abbreviations: P—protiodide of mercury $\frac{1}{8}$ - to $\frac{1}{4}$ -gr. doses; L—Lugol's solution; K—Potassium iodide; I—Subcutaneous injection of iodide; PNH—Pale nerve head; CI—Increase of lens opacities; CM—Cataract matured; FP—Fundus changes which could complicate the results obtained as listed in syllabus.

istered, each of which seemed equally effective. For this method 1 c.c. was injected subcutaneously twice or thrice weekly, so long as the vision continued to improve. When this point was reached

the injections were discontinued and oral administration as described above was given on alternate months. In a few cases it was necessary to give the injections on alternate months to maintain the im-

proved vision, for the vision would decrease when these patients were on oral administration.

Ten eyes improved when iodides were given by injection which had failed to show any improvement on oral administration.

In this series of 67 patients with a total of 115 eyes, which showed senile macular degeneration, the eldest was 87 years of age and the youngest was 52; the average age being 70.34 years. The longest any patient was under observation was five years, and the shortest period of observation was one month; the average time of observation was 15.13 months. The poorest original vision in this series was 0.03 and the vision of this eye increased to 0.1 under administration of 0.25 gr. of protiodide of mercury thrice daily. This vision was maintained for 11 months, when the patient was last seen. The most acute original vision included in this series was 0.9, and in these eyes foveal changes were present. Ten eyes were not improved by any method tried. Fifty-six eyes improved with oral administration. Ten eyes showed no change while under oral administration but did improve when iodides were injected subcutaneously. The average improvement of the 115 under treatment was 89 percent. The most marked improvement was from 0.04 to 0.9, which is 22.5 times the original vision. Subcutaneous injections were given in this case. In only 15 eyes were the lenses clear. In five eyes lens opacities increased appreciably while the patient was undergoing treatment, one cataract becoming mature. One eye had occlusion of two small branches of the inferior nasal artery and in another eye a small retinal hemorrhage was found adjacent to the macula. Seven discs showed a decreased capillarity. Two eyes had choroidal sclerosis and two showed scattered areas

of choroidal degeneration. All eyes had sclerosis of the retinal vessels to some degree and all had mild refractive errors with the exception of three aphakic eyes which required a high correction for compound hyperopic astigmatism. The vision in each instance was taken with the error of refraction corrected at that time.

It is interesting to note that 29 eyes showed a decrease in vision after the initial improvement. One of the 29 was under observation only two months (no. 48). Two eyes (no. 107 and 108) which were under observation 62 months did not show any decrease in vision.

An undetermined number of patients who were unable to read with the original vision but who could read with their improved vision, complained because they were able to read for short periods only.

Two cases are worthy of especial mention. The first was of a woman, aged 67 years, with incipient lens changes, moderate arterio- and arteriolar retinal sclerosis and stippled maculas, whose vision was 0.4 and 0.45. She was given protiodide of mercury, gr. 0.25 thrice daily, and three months later had attained a vision of 1.0 in each eye. At this time the medication was discontinued. Eight months later she reported with a vision of 0.2 in each eye and again protiodide of mercury, gr. 0.25 thrice daily, was prescribed. In three months her vision had increased to 1.1 and 1.2. She continued with this treatment and retained normal vision for two years, when the lens opacities increased, so that by the end of a third year her vision was 0.4 and 0.45. At this time the protiodide was discontinued and she was given 1 c.c. of camirol subcutaneously twice weekly. One month later her vision had improved to 0.75 and 0.7. She was not seen for six months when the vision had decreased to 0.55 and 0.45.

The second case was that of a man, aged 70 years, with incipient lens opacities, arterio- and arteriolar retinal sclerosis, and perceptible macular depigmentation, whose vision was 0.3 and 0.35. Protiodide of mercury, gr. 0.25 thrice daily, was prescribed, and his vision slowly decreased to 0.1 in each eye in 13 months. His cataracts had not increased and all fundus details could be seen perfectly. The protiodide was discontinued and 1 c.c. of homiodin was injected subcutaneously twice weekly. He was not see for six months, but the treatment was continued. When he was again examined the cataracts had increased so that fundus details were seen with difficulty. He insisted that his cataracts be removed. With considerable reluctance this was done. Following surgery his corrected vision was 1.1 in each eye. For the past three-and-one-half years he has taken protiodide, gr. 0.25 thrice daily, at irregular

intervals and his vision has varied from 1.1 to 0.9 in this space of time. When his vision decreases his medication is resumed, and each time his vision improves.

CONCLUSIONS

1. The conditions which produce senile macular degeneration are thought to be: (a) Senility, (b) heredity, (c) sclerosis of the choriocapillaris of the choroid. It is probable that heredity is the major factor in many instances, for it may predispose to either senility or to sclerosis of the choriocapillaris.

2. The administration of iodides did appreciably improve the vision in a majority of cases of senile macular degeneration in this series.

3. The mechanism by which this improvement is obtained is not known.

4. Large doses of iodides are not necessary to obtain satisfactory results.

ERRORS IN DIAGNOSIS OF INTRAOCULAR TUMORS*

(SUSPECTED OR REAL)

WILLIAM EVANS BRUNER, M.D.

Cleveland, Ohio

It is always a pleasure or satisfaction to report our successes in the treatment of any eye disease or good results after operations upon the eye.

A writer in the *British Journal of Ophthalmology* (June, 1943) makes a very truthful statement: "We have always held the opinion that one learns more from failures, our own as well as others, than from successes" and also adds "It always pays to listen to a patient's history, even if it may be very diffuse and to note the salient points in the history."

These truths will be evident in the history of the following cases.

Case 1. Mr. "A," aged 58 years, came for consultation on January 29, 1932, with the history of gradual failure of vision in the left eye for five years, during which time he was under the care of another oculist, who pronounced his condition as simple detachment of the retina. *Ophthalmoscopic examination* revealed a large, gray, smoothly rounded mass projecting far forward into the vitreous in the upper outer quadrant. There was an extensive detachment of the retina surrounding this mass, more elevated than the detachment elsewhere. With the pupil dilated it was possible to see all around the mass, which was very light, almost white in color. Transillumination showed a definite shadow. A diagnosis of "tumor" was made, and enucleation advised, and, because its color indicated that it was only mildly malignant, a favorable

prognosis was given. The eye was promptly enucleated and the pathologist reported a spindle-cell sarcoma with very little pigment—evidently not a very malignant type. When the patient was seen in August, 1943, some 11 years later, he was perfectly well, so that he has probably passed the danger from any metastasis, and the mistake in diagnosis and delay in operation has had no serious result.

Case 2. Mr. "B," aged 55 years, was referred to us on July, 1943, with the history of sudden loss of vision in his right eye a week previously, and the request of information and advice concerning operation. He stated that 10 days previously, while working in his victory garden but doing no heavy lifting, he noticed the vision of this eye suddenly become blurred. *Examination* showed a large, smooth, rounded elevation in the upper portion of the fundus, sharply defined, with no folds, partly covering the nerve and entirely concealing the macula. The fundus was normal elsewhere. The elevation rose abruptly and was sharply defined on the temporal and nasal sides but had no sharp demarcation above—no retinal tear nor hole could be seen. Transillumination revealed no shadow. Tension was 14-16 mm. Hg (Schiotz); vision was the perception of hand movements. A small disc could be seen above and to the nasal side, but the field was blind at fixation and below. Our diagnosis was a probable serous detachment of the retina, and we advised that the patient be put to bed in the hospital with complete rest, in the hope that the detachment might flatten so that it might be possible

* Read before the eightieth annual meeting of the American Ophthalmological Society, at Hot Springs, Virginia, May 29 to 31, 1944.

to see the hole or tear if such existed and then operate.

In February, 1944, six months later, the doctor reported that he had put the patient to bed as suggested, and as the detachment did not subside, he had performed a coagulation operation, following which the retina became reattached and vision improved. Two months later a new detachment occurred on the medial side of the former area, and the entire retina became detached. Several months later the patient reported to the doctor with "absolute glaucoma," tension 140 mm. Hg (Schiotz). The eye was removed, and the pathologist found a "melanotic" sarcoma of the choroid near the optic nerve. This patient illustrates how impossible it may be in some cases to make a definite diagnosis of intraocular tumor in the very early stages.

Case 3. Mrs. "C," aged 42 years, from a nearby city, came for consultation on October 10, 1938, with various diagnoses from different doctors and finally with a diagnosis of intraocular tumor by the referring oculist. She had noticed some defect of vision in the right eye for four years, without change, but she thought it may have always been a poor eye. She had had some inflammation of both eyes eight years ago, which lasted four or five months, and she said that this recurs in the summer if she becomes overheated. There had been no pain in the eye until the past week. She was wearing: O.D. -0.50D. sph. \approx -1.00D. cyl. ax. 165°; O.S. -0.75D. sph. \approx -0.50D. cyl. ax. 180°. With these lenses her vision was O.D. 6/6, O.S. 6/5, and she could readily read 0.50 print with either eye. Muscle balance was exophoria 8 degrees and left hyperphoria 4. Four years ago she had been treated with radium and deep X-ray therapy for carcinoma of the cervix. She had been checked 10 months ago and pro-

nounced all right and was due to return shortly for another check.

The pupils were equal and promptly reacted to light; tension was normal in each eye. *Ophthalmoscopic examination.* O.S., media clear, no pathologic changes in the fundus. O.D., with pupil dilated some vitreous opacities could be seen and some fine changes in the macula. Extending down and out from the macula there was a gray line and fold showing the beginning of a retinal detachment. This was not so sharply marked down and in. Directly below the nerve was a dirty-gray, indistinct, poorly outlined elevation or apparent growth, with several horizontal lines, like folds, over it. The vessels passing over it lacked the normal light reflex. The top of the elevation was plus 20 or more. No tear nor hole could be seen in the retina. Transillumination showed a very definite or dense shadow directly below. The tonometer recorded a tension of 15 mm. Hg. Our diagnosis was a probable intraocular tumor, and, from the history, we suspected it might be a carcinoma; hence made an unfavorable prognosis to the husband. As the patient was due for a check up by the doctors who had treated her for the carcinoma of the cervix we advised that she see them promptly in order to determine the condition of the cervix—whether there had been any local recurrence at the seat of the original lesion and whether there was any indication of metastasis elsewhere. They reported that they found a rent far below, believed it to be a serous detachment, and advised trying operation. This was performed on October 24th. When the patient left the hospital a month later, the referring ophthalmologist wrote: "The retina appears to be completely reattached," and he was unable to see any definite evidence of tumor. "I have tried," he further wrote, "to make it clear to her that in spite of the at present suc-

cessful result of the surgery there is a remote possibility of a tumor showing up." She was seen by another oculist in this city in July, 1939, when there was pain in the left eye. His examination showed a deeply pigmented mass below with a definite shadow, detachment and wrinkling of the retina in the superior nasal area, and hemorrhage on the temporal side. He saw her again on April 9, 1940, a year and a half later, at which time she had what he thought was a large area of retino-choroiditis in the lower part of the fundus. Vision was 6/21.

It looks in this case as though we had been wrong in our diagnosis, but two questions arise in my mind: Will a serous detachment give a dense shadow in transillumination, and does the presence of a rent or hole in the retina exclude a tumor? Personally, I cannot see why in a detachment of the retina surrounding a growth there might not be a rent from the pulling upon or stretching of the retina. We have no subsequent history of this patient and know nothing of the remote possibility of a tumor showing, as the operating doctor suggested.

Case 4. Mrs. "D," aged 55 years, came from an adjoining city, on March 8, 1939, referred by an oculist from her home town who had found some serious trouble with the right eye. She reported a marked change in the refraction of this eye. As a result of her last examination she was wearing O.D., $-1.50D.$ sph. $\approx -0.50D.$ cyl. ax. 180° ; O.S., $-0.75D.$ cyl. ax. 135° with a $+2.00D.$ sph. added O.U. for reading. With these, vision was O.D. 5/5, O.S. 5/4, and accommodation was equal in the two eyes. External examination was negative. The pupils were equal, and reacted promptly to light. The tension was normal, and the field normal in each eye except for a slight contraction down and in, in the right eye. *Ophthal-*

moscopic examination O.S. was normal. O.D. with pupil widely dilated there were seen many dustlike opacities in the vitreous; the disc was hazy but of good color. The fundus was normal except in the upper outer quadrant where there was a large prominent detachment of the retina with sharp lower border. The detachment appeared irregular, not smooth—no tear was seen. Transillumination showed a very definite shadow far back at the 11:30-o'clock position. The patient was seen again a week later. Vision did not seem to be so good. The appearance was practically as before—a prominent detachment up and out; directly out the lower horizontal margin of the detachment was sharply defined; up and in, it faded off irregularly into the surrounding retina. Transillumination showed a positive shadow as before. She was advised to see an oculist in another city for further opinion.

This doctor wrote that in his opinion, the patient had a serous detachment of the retina. He found the whole area translucent and could also see a tear in the retina. He operated upon the eye, shutting off the hole, and when she returned in May, two months later, her vision was 20/30 and the retina was in place. In June, in reply to my letter, the oculist who had originally referred her to us reported that up to the present time there is no evidence of a tumor and there is no further detachment.

Evidently, in this case, the error was in our office. There was definitely a difference of opinion in regard to a shadow and a retinal tear. Again the question arises about a serous detachment causing a shadow in transillumination and the importance of a tear in the differential diagnosis between a tumor and a simple detachment.

Case 5. Mr. "E," aged 27 years, was

seen in consultation, on December 31, 1921, in his bed at home. We were called by the physician's assistant. The patient had upon several occasions been fitted for glasses to correct some compound hyperopic astigmatism, with resultant normal vision, and had had no trouble otherwise with the eyes. Three or four days before we saw him, he had noticed a blur before his left eye, which came on rather suddenly without any apparent cause. There was no history of injury to the eyes or head nor of any physical strain. He had been using the eyes only moderately. The assistant saw him on the day the blur was first noticed, and made a diagnosis of detachment of the retina. The pupils were widely dilated with atropine; vision sufficed only to count fingers at a short distance. The field was contracted almost to fixation in all directions. Tension was normal or slightly less than in the right eye. *Ophthalmoscopic examination*, O.D., disclosed nothing pathologic; a low hyperopia. O.S., the media were clear; the disc was round, more hazy than in the right eye, especially at the inner edge, hyperemic, and the retina striated. Directly above was a large smooth regularly rounded mass projecting far forward into the vitreous. It rose very abruptly, the vessels could be seen passing over it. There was no detachment, fold, nor irregularity in the retina surrounding it. Transillumination directly above and well posterior showed a very definite dark shadow, whereas to either side of it and from all other directions there was good illumination. A diagnosis of probable sarcoma of the choroid was made, and the patient was advised to have another examination by his regular oculist, who was returning very shortly, and if our findings were confirmed, to have the eye enucleated. His oculist considered it a simple detachment and made a scleral puncture. He reported on December 18,

1922, almost a year later, that the eye had steadily improved after the operation, but we had no opportunity to make an examination. Later, when the patient was having some discomfort, he consulted another Cleveland oculist who found the tension increased and sent him to an oculist in another city, who, in late 1924 or early 1925, trephined the sclera over the site of the lesion. Later he was seen by a still different oculist in Cleveland, who found a well-marked nodular mass in the vitreous and tension 34 mm. Hg, with slight discomfort. He made a diagnosis of intraocular growth and advised enucleation. The patient returned to the oculist who had trephined the eye the year before, and in January, 1926, this oculist removed the eye and found a tumor within the globe. He informed the patient that the tumor was of very recent growth, although I had made the diagnosis of it four years previously. Unfortunately, I do not know what type of tumor the pathologic examination revealed. We saw the patient for simple conjunctivitis in the right eye in 1927, and at that time there was no sign of metastasis elsewhere, a danger which, I felt, had naturally been increased by the long delay. The interesting feature of the case was the long interval between the time when we first saw him and made the diagnosis of the intraocular tumor, and the time when the eye was finally enucleated—a period of more than four years. When we last talked with him over the telephone in 1944, 18 years later, he was in good health, so that evidently the tumor was of the non- or low-malignant type.

Case 6. Miss "F," aged 18 years, accompanied by her father, a physician, first consulted us in January, 1927. There was a history of forceps at birth and a contusion of the right upper lid. When she was four or five years old, the parents

noted a slight squint. She was taken to an oculist who told them that the eye was blind. The slight squint continued and varied at times, being more marked when she was tired or not well. She had a strenuous time during the Christmas holidays, attending parties, and spent several days in bed. Upon returning to school she was again in bed for several more days and the nurse noticed the pupil of the right eye was larger than the left. She began having some inflammation and pain in the eye. This became so severe one night that the following morning she consulted a local oculist who told her that he suspected a "neoplasm" in the eye. She returned home at once and was brought to the office.

Examination showed vision in the right eye to be light projection; O.S. 6/5. There was marked strabismus in the right eye with limitation of outer movement. All other movements were normal. The iris was slightly discolored, with several large vessels on the surface and ectropion of the iris pigment around the entire pupillary margin. The pupil was widely dilated above, while below there was a broad posterior synechia; only slight bulbar conjunctival injection. By oblique light, some slight reddish reflex could be made out on the extreme nasal side with numerous glistening spots like cholesterol crystals giving it a mottled appearance; all seen best with a strong plus sphere. A gray reflex showed through a veil directly above, while far to the outer side and above was a gray reflex like extensive exudate with several vessels over it. Directly in the center and below there was no red reflex, only a dense opacity. The slitlamp confirmed these observations. The anterior layers of the cornea were clear; on the posterior surface were a very few fine pigment dots and a few smaller dots on the anterior capsule of the lens. The lens itself showed

nothing abnormal. A fine, apparently organized, semitransparent film could be seen in the vitreous with a large denser mass on the nasal side, blood color. To the outer side the vitreous was more gray or more densely organized with even darker spots, some brown, some slightly reddish, but no definite mass could be distinguished.

Transillumination showed a dense shadow over this area, and good red reflex from all other directions. Oblique light showed a grayish mass with some reddish spots in the lower portion of the fundus. The tonometer reading was 44 mm. Hg (Schiotz).

On the day following, her first visit, I learned that on the day before she first noticed this eye trouble, she had had a fall while skiing and struck the right side of her body and head. This suggested the possibility of an intraocular hemorrhage. I also learned from her oculist, who had seen her in childhood, that ophthalmoscopic examination at that time showed all media clear and an extensive rupture of the choroid involving the macular region with much disturbance and atrophy of the choroid throughout the fundus. Only two years before I saw her, the vitreous, he reported, was clear and there was no sign of iritis. Hot packs were ordered. There was no change the following day, the tension was still 44 mm. Hg. The patient was advised to continue the hot packs, keep quiet, and report. Three days later she was having no discomfort whatever and examination showed no change. Potassium iodide was added to the treatment and the hot packs continued. Four days later she was having no discomfort. Ophthalmoscopic examination showed the same general appearance except that the vitreous was not so dense and more red reflex could be seen in the periphery below, in and out. Transillumination showed the same shadow. I had felt that

the condition was most probably due to an intraocular hemorrhage from the fall and was treating her accordingly. Her age also pointed against the probability of a tumor. The father decided he would like a consultation, to which I gladly acceded, and gave him a letter explaining that the present trouble seemed to have started as the result of a fall in skiing and the history would suggest an intraocular hemorrhage (though other symptoms pointed to an intraocular growth). The interior had shown no change except that the vitreous did not appear so dense as at the first visit and all pain had ceased.

The father took her to another oculist and apparently did not show my letter suggesting an intraocular hemorrhage. Finding a detached retina, dense shadow in transillumination and increased tension, and without the history of the probable cause of onset, the importance of which I stressed in the letter, he concluded it was an intraocular growth and removed the eye the following morning. The father wrote me "there was a growth and I heard some talk of a secondary glaucoma." I was still unwilling to accept this diagnosis, and in March, 1935, eight years later, I finally received a report on the pathologic findings. These showed: "No tumor but a subretinal space filled with a large blood clot containing many cholesterol crystal spaces, and absolute glaucoma." Possibly no other treatment than enucleation would have given her permanent relief, but our original diagnosis of intraocular hemorrhage rather than intraocular tumor was confirmed.

This case illustrates the importance of a careful history in arriving at a correct diagnosis. Later I had the satisfaction and pleasure of informing the father, who had never received a report of the pathologic findings, that he need have no

further anxiety about the possibility of metastasis.

Case 7. In this last case to be presented there was no error in the diagnosis but rather a mistake on the part of the patient in not consenting to enucleation when first seen.

Mrs. "G," aged 57 years, came for consultation on September 14, 1908. Vision was O.D. 6/30; O.S. 6/7.5. Five or six weeks previously she had noticed a blur before the right eye on the temporal side. *Ophthalmoscopic examination* revealed an extensive detachment of the retina up and in, with a dense shadow on transillumination. The eye appeared normal externally. There was no discomfort. Tension was normal. The patient was told of the tumor and enucleation was advised, but she was not willing to have the operation. After several subsequent visits, with symptoms each time becoming more evident, she finally consulted us again on March 13, 1909, six months later, when she was having some discomfort and no light perception. Examination showed only red reflex and no view of the fundus. She then consented to the operation and the eye was promptly removed.

The pathologist reported a pigmented spindle-cell sarcoma of the choroid and gave a guarded prognosis as to recurrence.

Four and one-half years later she was reported at Charity Hospital, with extensive growth on the liver—evidently metastasis.

The question arises in this case, whether there might have been a different final outcome if she had consented to the operation six months earlier, at the time of her first visit.

The Guardian Building.

SOME OBSERVATIONS UPON THE CHEMICAL NATURE OF THE PTERYGIUM*

HOWARD H. BEARD, PH.D., AND THEODORE J. DIMITRY, M.D.
New Orleans

Merigot de Treigny and Coirre¹ define the pterygium as follows: "An ocular disease which is characterized by a membranous growth on a level with the bulbar conjunctiva. It is opaque, more or less vascular, habitually triangular, and generally situated in the palpebral aperture. The body spreads fanlike and is movable on the sclerotic which it covers (cf. fig. 1). The disease can lead to blindness by a total encroachment over the pupillary zone and frequently recurs when operated upon."

A complete description of the disease is given by these French ophthalmologists. Duke-Elder² stated that the "fully developed pterygium is covered with conjunctival epithelium, stratified with flat cells on the surface of the head and neck. Goblet cells are numerous in the depressions which form glands which may develop into cysts. Throughout the epithelial layer there may be pronounced pigmentation. The stroma is similar to normal sub-epithelial tissue. It is dense and cellular near the apex, elastic fibers are numerous, and patches of amyloid and hyaline degeneration are usually evident" (cf. fig. 2).

Fuchs was probably the only early investigator who made an attempt to study the chemical nature of the stroma of the pterygium. He observed that the hyaline substance was characterized by its homogeneous character, its refractive power, its resistance to acids and alkalis, and by its deep staining with carmine, picro-carmine, and with eosin.

Pterygia are frequently observed on the Ophthalmologic Service of the Char-

ity Hospital. If choline chloride is topically applied to the pterygium its head will become altered.³ For this reason it was deemed advisable to attempt a study of the chemical make-up of these pathologic growths. Our tests were few, due to the limited amount of material available.

Fig. 1 (Beard and Dimitry). A pterygium.

Three pterygia, very soon after surgical removal from the eye, were boiled out with chloroform in a beaker of hot water. The Salkowski reaction for cholesterol ($\text{CHCl}_3 + \text{H}_2\text{SO}_4$) was very faint but deepened on standing for one or two days. Precipitation with digitonin was unsuccessful owing to the minute amount of cholesterol present. The amount of chloroform-soluble material present in the fresh pterygia is given in table 1.

Our balance was sensitive to about ± 1 mg. For this reason the figures in the second decimal place in the table are estimates. The presence of about 50 percent of the pterygium as chloroform-

pterygium is shown in figure 1 and its border in figure 2. Figure 3 shows the residue obtained of the chloroform-soluble material stained with Sudan III. Figure 4 shows the transparent residue left of the pterygium after chloroform extraction.

SUMMARY

Three pterygia were studied after surgical removal. Their average weight was about 8 mg. The chloroform-soluble material amounted to about 47.5 percent of the fresh weight of the growth. A positive Salkowski reaction for cholesterol was obtained, but the amount present was too small to be precipitated with digitonin. The action of choline chloride in causing these growths to become altered is discussed together with a new etiology of the disease.^{5, 6, 7}

TABLE 1
CHLOROFORM-SOLUBLE MATERIAL PRESENT IN
FRESH PTERYGIA

Sample No.	Weight mg.	CHCl ₃ Soluble Material mg.	Residue mg.
1	6.6	2.9	3.7
2	7.7	3.2	4.5
3	9.2	5.1	4.1
Average	7.8	3.7	4.1

occurred. The blood vessels of the body of the growth became greatly engorged with blood and the fatty substances disappeared. Evidently the formation and transportation of phospholipids occurred here as is the case when choline removes the fatty material from liver (its lipotropic action).⁴ From these results one may be justified in asking the question, "Is the formation of the pterygium due to a choline deficiency in adults?" This is possible since choline gives dramatic results and the irritation theory of the formation of the pterygium is no longer held.³

BACTERIOLOGIC STUDY OF HUMAN CONJUNCTIVAL FLORA*

FRANK H. RODIN, M.D.

San Francisco

The bacterial flora of the human conjunctiva has been studied in Europe and elsewhere from the beginning of this century, and has also been the object of intensive research in the eastern, southern, and central sections of the United States. To our knowledge, however, such a program has never before been undertaken on the Pacific Coast, and the survey made by the Department of Ophthalmology and the Clinical and Research Laboratories of Mount Zion Hospital in San Francisco, therefore, is the first to be reported in this area.

It is known that the conjunctiva of the newborn is normally sterile, and that it later becomes subject to invasion by bacteria. Classification of these organisms into pathogenic and nonpathogenic for the conjunctiva has been more or less well established. The intact ocular mucous membrane is protected histologically by its tissue structure, mechanically by the cleansing action of winking, and chemically by antibodies and the bactericidal properties contained in tears, chiefly from lysozyme. It is interesting to note that lysozyme, an enzyme, was first described in 1922 by Alexander Fleming, who, in 1929, discovered penicillin.

In the presence of reduced tissue resistance due to trauma or abnormality, however, such organisms may invade the

conjunctiva, colonize there, and produce local inflammation or infection. Some types of conjunctivitis can be adequately diagnosed clinically. However, the exact etiology of others is determined only by bacteriologic study of conjunctival scrapings. A microdiagnosis so obtained is often of inestimable value in making possible the correct diagnosis, a more accurate prognosis, and institution of proper treatment. It is also a vitally important preliminary measure in planning intraocular operations. A normal-appearing conjunctiva may be discovered to harbor flora which, though nontoxigenic to the sound conjunctiva, may prove toxigenic to the anterior chamber into which they are likely to be carried by the surgeon's knife. With this information available, appropriate prophylactic therapy can be effected. Since we are limiting this paper to bacteriologic observations, treatment will not be discussed here.

Our analysis is based on bacteriologic findings in 152 cases of clinically normal conjunctivas and acute and chronic conjunctivitis from birth to 80 years of age. Although our results substantiate for the most part those published by early authors, improved knowledge of bacteriology and modern methods of culture have yielded a number of microorganisms rarely recorded as residing on the human conjunctiva. They have also proved the absence of certain others, such as the Koch-Weeks and Morax-Axenfeld bacilli. Our statistics conform quite closely to those from other communities, with the noteworthy exception that the pneumococcus was isolated from only two of our patients.

*From the Department of Ophthalmology and the Clinical and Research Laboratories of Mount Zion Hospital, San Francisco. This research was aided by a grant from the Columbia Foundation. Read before the Section on Eye, Ear, Nose, and Throat, at the Seventy-third Annual Session of the California Medical Association, Los Angeles, May 8, 1944.

BACTERIOLOGIC STUDY OF HUMAN CONJUNCTIVAL FLORA

TECHNIQUE

Our technique of bacteriologic study was as follows:

Culture methods. The conjunctiva and cornea were anesthetized with repeated instillations of 0.5-percent pontocaine. Topical scrapings were made of the palpebral and bulbar conjunctiva with the aid of a platinum spatula (fig. 1). A small sterile swab, moistened with sterile broth, was also used for collecting material. Culture media were inoculated first, and the scrapings were carefully placed on glass slides and stained by Giemsa and Gram stains.

Depending upon the type of infection suspected, media were selected that were suitable for the growth of various bacteria, both anaerobic and aerobic, and fungi. Cultures were inoculated at both 37° and 22°C., since the latter more closely approximates the temperature of the conjunctiva.

The routine medium employed contained Difco proteose peptone (No. 3) and 5-percent rabbit's blood. For the purpose of promoting the growth of hemoglobinophilic bacteria, cooked blood agar was used. The anaerobic bacteria were cultivated in tubes of thioglycolate

broth, and also on blood agar in S₁ dishes. Heart infusion broth was used as a duplicate to permit development of aerobes, and Loeffler's slants for the isolation of the Morax bacillus and related organisms. Cornmeal agar served for the growth of fungi.

The material removed by scraping was

Fig. 1 (Rodin). Platinum spatula used to obtain scrapings from the conjunctiva.

diluted serially, and some of it was exposed for 10 to 15 minutes to the action of an aqueous solution of 1 to 20,000 to 1 to 40,000 crystal violet (to permit intrinsic bacteriostasis of a variety of Gram-positive bacteria) before being cultured. The remainder was inoculated directly into the aforementioned media.

Animal inoculation. For the detection of the virus of herpes, some of the material removed from the patient was inoculated into the scarified cornea of a rabbit. The pathogenicity of organisms isolated was tested by subconjunctival and

* There were 5 cases of inclusion blennorrhoea in newborn infants, 1 *Streptococcus viridans*, and 1 pneumococcus, type III. One case of *B. pandora*, 1 of *Sarcina*, 1 of *pseudomonas*, 2 of *Alcaligenes*, and 1 of *Gaffkya tetragena* were discovered.

intraocular injection of similar animals.

Serologic tests. When lymphogranuloma venereum or gonococcal infection was suspected, the patient's serum was subjected to complement-fixation tests. Agglutination reactions were performed for the diagnosis of brucellar or leptospiral infections.

BACTERIAL FLORA OF NORMAL CONJUNCTIVA

Cultures from 42 clinically normal conjunctivas were examined bacteriologically. To these patients' knowledge, and according to their case histories, they had had no ocular disturbances. The organisms most commonly recovered were staphylococci (76 percent) and diphtheroids (50 percent), usually in combination. The parallel incidence of these two bacteria was seen to be lowest at an age between 20 and 40 years, highest in the 50-to-60-year age group, and to remain consistently elevated thereafter. Mixed cultures were fairly uniform in incidence throughout the span, and were noted in 40 percent of all eyes examined. These findings vary insignificantly from those of Khorazo and Thompson,¹ who

report an increase in diphtheroids and mixed cultures in direct ratio with the age of the patient, particularly accentuated in the 30-to-49-year classification (38 percent). *Alcaligenes* was present in one case and *Streptococcus viridans* in another. No *Streptococcus*, pneumococcus, or *Sarcina* was isolated. Occasionally in these eyes, bacteriologic study fails to reveal any growth whatsoever, but this is a rare occurrence (8 out of 42 cases, 20 percent). On the other hand, many organisms may be present on conjunctivas exhibiting no clinical evidence of inflammatory reaction. This is particularly true of *Staphylococcus*, which is known to be an inhabitant of most normal conjunctivas. Some strains of both *Staphylococcus aureus* and *Staphylococcus albus* are considered toxin producing and others nontoxin producing,² and the object of bacteriologic examination is to determine which strains are present in a given eye.³ In our experience, the coagulase test yields the most reliable results. The problem of diphtheroids has been studied, and a report of the findings is now in the process of publication.

BACTERIAL FLORA OF ACUTE
CONJUNCTIVITIS

Twenty-five cases were studied. Here as in clinically normal eyes, *Staphylococcus* and diphtheroids predominate. In addition, *Streptococcus nonhaemolyticus* appeared twice, and *Streptococcus haemolyticus* once in 25 patients. An unusual finding was that of *B. pandora*. A scraping from a rubber plant owned by the patient revealed an identical growth. A single case each of *Sarcina*, *pseudomonas* and *Gaffkya tetragena*, and two cases of

Alcaligenes were present. Only one case of pneumococcus was isolated in an infant, whereas in Thygeson's⁴ report this organism was the most frequent source of infection in acute and subacute conjunctivitis in Iowa. In San Francisco,⁵ the *Staphylococcus aureus*, hemolytic and toxigenic, seems to be the most frequent etiologic agent in conjunctivitis of a certain clinical type.

The bacteriologic examination in conjunctivitis of 13 newborn infants revealed 5 cases of inclusion blennorrhea.

TABLE 3
BACTERIAL FLORA OF CONJUNCTIVITIS OF THE NEWBORN

Name	Age	Clinical Data	Bacteriologic Observations
1. T.	5 days	5 days after birth, child showed purulent discharge from both eyes; father had gonorrheal urethritis; mother had vaginal abscess during pregnancy.	Vaginal smear of mother negative; scrapings from baby's tarsal and bulbar conjunctivas showed epithelial-cell inclusions characteristic of inclusion blennorrhea; no bacteria on smear or culture.
2. J.	21 days	13 days after birth, swelling and discharge, left eye; right eye involved; 8 days later, lids edematous and red; purulent secretion.	Cytoplasmic bodies characteristic of inclusion blennorrhea; <i>Staphylococcus albus</i> nontoxigenic.
3. P.	3 days	3 days after birth, purulent secretion from right eye.	Smear, few epithelial cells, no bacteria nor inclusion bodies; culture, several colonies of <i>Staph. albus</i> , occasional colonies of <i>Str. nonhaemolyticus</i> and <i>Str. viridans</i> , also a few diphtheroids.
4. M.	23 days	Purulent discharge from right eye.	Gram stain, many pus cells, no bacteria, no inclusion bodies; culture, <i>Staph. albus</i> and a few diphtheroids.
5. T.R.	11 days	Purulent discharge from left eye.	Smear, gram-positive cocci and leucocytes, also few gram-negative rods; culture, <i>Staph. aureus haemolyticus</i> .
6. N.	2 days	Purulent discharge from both eyes.	Smear, epithelial cells, diphtheroid bacilli, no inclusion bodies; culture, <i>Staph. albus</i> and diphtheroids.
7. G.	2 days	After birth, greenish discharge from both eyes.	Culture, <i>Staph. albus haemolyticus</i> , <i>Staph. aureus</i> and diphtheroids.
8. K.	2 days	Conjunctivitis, left eye, at birth; eczema of face.	Direct smear, no bacteria; culture, <i>Staph. aureus</i> .
9. C.T.	7 mos.	Infection began 3 days after birth, with purulent discharge.	Pneumococcus, type III.
10. C.	1 day	2 hours after birth, swelling and discoloration of upper lids, especially of left eye; purulent secretion.	Direct, smear, numerous white blood cells; culture, no growth.
11. Z.	2 mos.	10 days after birth, lids were sticking with secretion. Conjunctiva red.	Inclusion bodies suggestive of inclusion blennorrhea.
12. W.	5 wks.	Discharge right eye for 1 wk. Eyelids swollen.	Typical inclusion bodies present and diphtheroids.
13. L.	14 days	Left eye red with discharge; difficulty in opening eyelids.	Inclusion bodies suggesting inclusion blennorrhea.

This infection of the newborn is caused by a filtrable virus, and is a distinct clinical entity occurring acutely 5 to 10 days after birth. It is very important to differentiate microscopically between inclusion blennorrhoea of the newborn and ophthalmia neonatorum of gonococcal origin.⁶ These infants were seen in an acute stage of the disease, and showed severe inflammation, edema, and infiltration of the conjunctiva, and purulent

through 60 years. *Haemophilus influenzae*, *Bacillus subtilis*, *Micrococcus catarrhalis*, and *Bacillus mutabilis* were isolated once each from patients 40 to 70 years of age. Children are usually free from chronic conjunctivitis. A five-year-old child was the youngest to be affected in this series.

Culture study in chronic conjunctivitis is at times of tremendous value in diagnosing the underlying cause.⁷ For example, a patient proving refractory to treat-

TABLE 4

* There were 2 cases of lymphogranuloma venereum; 2 of trachoma; 5 of *Gaffkya tetragena*; 1 of *Alcaligenes*; 1 of *Haemophilus influenzae*; 1 of *Bacillus subtilis*; 1 of *Micrococcus catarrhalis*; 1 of *Micrococcus mutabilis*.

discharge. It is interesting to note that in one case the father had a gonorrheal urethritis, and the mother a vaginal abscess during pregnancy.

Other bacteriologic findings in the newborn are described in table 3.

BACTERIAL FLORA OF CHRONIC CONJUNCTIVITIS

Eighty-five cases of chronic conjunctivitis were studied. *Staphylococcus* and diphtheroids still dominate the picture, and their incidence increases with advancing age. The *Streptococcus* was recovered only twice, but *Sarcina* and *Gaffkya tetragena* were quite constant in a small proportion of eyes from one

ment for conjunctivitis was referred for bacteriologic examination. Microscopic study of the growth from conjunctival scrapings revealed trachoma as the primary infective agent, and *Staphylococcus* secondary. *Staphylococcus* is frequently superimposed in trachoma infections, and the latter should be suspected in long-standing cases. Our patient was a 52-year-old woman who worked in a clinic as a nurse's aide, treating Indians who were infected with trachoma. Laboratory findings showed *Staphylococcus aureus* haemolyticus and diphtheroids. Inclusion bodies suggestive of trachoma were found. The second patient was a man, aged 72 years, with chronic conjunctivitis

TABLE 5

BACTERIAL FLORA OF CONJUNCTIVAS PRIOR TO CATARACT EXTRACTION

	Name	Age	Eye	Bacteriologic Findings
1.	C.F.	74	R.E.	Staph. albus nonhaemolyticus.
2.	G.M.	60	L.E.	One colony of Staph. albus nonhaemolyticus; 50-100 colonies diphtheroids.
3.	A.O.	61	R.E.	Few colonies Staph. albus hemolyticus; diphtheroids.
4.	B.H.	54	R.E.	Staph. albus haemolyticus, nontoxigenic. Staph. aureus haemolyticus, nontoxigenic.
5.	A.M.	40	L.E.	No bacterial growth.
6.	M.M.	65	R.E.	Staph. aureus nonhaemolyticus; diphtheroids.
7.	A.N.	48	R.E.	No bacterial growth.
8.	A.N.	49	Tabes L.E.	3 colonies of Str. viridans and diphtheroids. Some colonies Staph. albus.
9.	L.R.	36	R.E. Myotonia dystrophia	Several colonies of Staph. albus.
10.	L.R.	37	L.E. Myotonia dystrophia	Several colonies of Staph. albus.
11.	H.S.	38	L.E.	One colony Staph. albus.
12.	D.F.	52	L.E. Injection of bulbar con- junctiva	Profuse growth of Staph. albus, nontoxigenic. Following treatment no growth 10 days later.
13.	J.M.	72	L.E.	Staph. aureus haemolyticus, toxigenic; 100 colonies. Following treatment, 20 days later 1 colony Staph. aureus haemolyticus, toxigenic.
14.	A.R.	64	L.E.	Cataract extracted from right eye elsewhere with vision 20/30. 6 years later eye became red with hypopyon, panophthalmitis developed, eye enucleated. Left eye scheduled for surgery. Clinically conjunctiva normal, culture showed 150 colonies Staph. albus (nonhemolytic) and 50 colonies diphtheroids. Operation postponed. 4 days later acute conjunctivitis developed. 2 months later culture revealed 25 colonies Staph. albus and 8 diphtheroids. Month later culture showed few colonies of Staph. albus. Preliminary iridectomy done. 6 days after operation eye became red with purulent discharge from conjunctiva. This cleared up. Later cataract extracted without complications.
15.	E.E.	82	L.E.	Staph. albus and aureus haemolyticus, numerous. After treatment, 20 colonies Staph. albus and 2 colonies Staph. aureus haemolyticus; 6 colonies diphtheroids.
16.	G.O.	70	R.E.	Cataract removed without culture study, followed by infection. Dense membrane formed. Before discission, few Staph. albus nonhaemolyticus. Vision obtained 20/40.
17.	E.B.	71	L.E. Simple glau- coma with trephining Eyeball injected	Three colonies Staph. albus.
18.	C.D.	69	L.E.	One or 2 colonies Staph. albus.
19.	M.B.	82	L.E.	Three colonies Staph. aureus haemolyticus, toxigenic. As the conjunctiva was clinically normal, patient was hospitalized. During the night, the eye became red. Culture taken 10 days later showed few colonies of Staph. aureus. Rehospitalization; eye again became red. Culture study later showed 80 colonies of Staph. aureus haemolyticus. Treatment. Cultures showed no growth.
20.	W.L.	63	R.E.	Few colonies Staph. albus.
21.	A.M.	41	R.E.	No bacterial growth.

of one year's duration. Cultures revealed *Escherichia coli* and a nonhemolytic *Streptococcus* not corresponding to Lancefield's groups A, B, and C. Suspicious-looking inclusion bodies suggesting trachoma were present.

The two cases of lymphogranuloma venereum are of interest. These occurred in Negroes 32 and 33 years of age, in whom a clinical diagnosis of chronic conjunctivitis, corneal ulcers, and hypopyons had been made. Complement fixation with psittacosis antigen indicated the presence of lymphogranuloma-venereum infection. Cultures yielded hemolytic and nonhemolytic staphylococci.

BACTERIAL STUDY OF CONJUNCTIVA PRIOR TO CATARACT EXTRACTION

There is no uniformity of opinion as to whether or not a bacteriologic study of the conjunctiva should be made before cataract extraction. Some surgeons hold that if the eye is clinically normal and there is no obstruction to the nasolacrimal apparatus, the eye may be considered safe for operation. If the eye is not clinically normal, and if under treatment the infection cannot be cleared up, a culture study is then of value to determine whether bacteriologic conditions make operation a safe procedure. Others prefer to have bacteriologic studies made prior to every intraocular operation.

Browning,⁸ who has made an extensive bacteriologic study of eyes at the Moorfields Hospital, emphasizes the importance of a preoperative bacteriologic study. "Bacterial infection is one of the causes of failure following the operation of cataract extraction. It was the cause of the loss by removal of about 1 per cent of the eyes operated on for cataract at Moorfields. . . . With modern bacteriological methods, most, if not all of these cases could be avoided, and I think that if all conjunctival sacs were bacteriologi-

cally examined before operation there would be fewer postoperative infections, or infections during the operation."

Our policy has been to advise postponement of cataract extraction when six or more colonies of *Staphylococcus haemolyticus* toxigenic, or two or more of *Streptococcus haemolyticus*, pneumococcus, or *Bacillus pyocyaneus* are present.

Table 5 presents data on 21 consecutive cases of cataract, of which 20 were studied bacteriologically before extraction. Of these, 18 had clinically normal conjunctivas. In 16 cases, there was either no growth or only a few colonies—not sufficient to justify postponement of the operation. Case 13 showed 100 colonies of *Staphylococcus haemolyticus* toxigenic, which cleared up under treatment.

Case 14 is of interest. A cataract was extracted from the right eye, with vision obtained of 20/30. Six years later the eye became red with hypopyon. Panophthalmitis developed and the eye was enucleated. One year later the left eye was scheduled for a cataract extraction. Clinically the conjunctiva was normal. However, a culture showed 150 colonies of *Staphylococcus albus* (nonhemolytic) and 50 colonies of diphtheroids. The operation was postponed. Four days later the patient developed an acute catarrhal conjunctivitis. Two months later a culture revealed 25 colonies of *Staphylococcus albus* and 8 of diphtheroids. One month later culture showed only a few colonies of *Staphylococcus albus*. A preliminary iridectomy was done. Six days after the operation the eye became red and there was a purulent discharge from the conjunctiva. This cleared up. The patient was treated with autogenous *Staphylococcus* vaccine. Later cultures showed a few colonies of *Staphylococcus*, and the cataract was extracted, without complications.

The patient in case 15 had numerous

colonies of *Staphylococcus aureus* and *albus haemolyticus*, which also disappeared under treatment.

Case 19 was that of an obese female, 82 years of age, who had bilateral cataracts. Culture study showed three colonies of *Staphylococcus aureus haemolyticus* toxigenic. As the colonies were few, and the conjunctiva was clinically normal, she was hospitalized. During the night the eye became red. Culture taken 10 days later showed a few colonies of *Staphylococcus aureus*. She was again hospitalized, and during the night the eye again became red. Culture study later showed 80 colonies of *Staphylococcus aureus haemolyticus*. The eye was treated, and subsequent cultures showed no growth. There was no infection following cataract extraction.

There were two eyes which clinically showed injection of the conjunctiva. Case 12 displayed a profuse growth of *Staphylococcus albus nonhaemolyticus*. Ten days later, following treatment, there was no growth.

Case 17 was of a patient who had simple glaucoma of the left eye where a trephining had been done. After the trephining, the tension remained normal. Adhesions between the iris and the lens took place, and a secondary cataract formed. The eyeball appeared to be injected. The culture showed three colonies of *Staphylococcus albus*. In view of the few colonies present, it was felt safe to extract the cataract. This was done without subsequent infection.

The patients in all cases reported here were operated upon without infection following cataract extraction, with the exception of case 14 and case 16. In case 14 there was a purulent conjunctivitis six days after a preliminary iridectomy. In case 16 the cataract was extracted without a previous culture study having been made. Postoperatively, an acute

iritis developed, with the formation of a dense membrane. Nine months later, culture showed a few colonies of *Staphylococcus albus nonhaemolyticus*, and dissection was done. Vision obtained was 20/40.

SUMMARY

1. Bacteriologic study of the conjunctiva is of inestimable value in the diagnosis, prognosis, and treatment of infection of the conjunctiva, especially of clinically obscure conditions. It is important in determining the safety of operation on potentially infected eyes presenting cataract.

2. An analysis of 152 cases including persons with normal conjunctivas, acute and chronic conjunctivitis, and precataract-extraction conjunctivas so studied is presented. Bacteriologic investigation of conjunctival scrapings was carried out by the technique described.

3. The organisms most commonly recovered from clinically normal conjunctivas were *Staphylococcus aureus* and *albus*, hemolytic and nonhemolytic, toxigenic and nontoxigenic, and diphtheroids. More than one organism was present in almost half the cases. Notable was the absence of Koch-Weeks and Morax-Axenfeld bacilli.

4. Certain clinical types of acute conjunctivitis in San Francisco are marked by the predominance of *Staphylococcus aureus* (hemolytic and toxigenic), and of diphtheroids. Cultures demonstrated five cases of inclusion blennorrhoea of the newborn. A single case of pneumococcus, type III, was discovered in an infant.

5. In chronic conjunctivitis, *Staphylococcus* and diphtheroids are the most frequent findings, increasing in incidence with advancing age. Two cases of trachoma and two of lymphogranuloma venereum, referred with a diagnosis of chronic conjunctivitis, were diagnosed with the

aid of laboratory procedures. Staphylococcal infection was superimposed in all.

6. Twenty-one consecutively studied cataract cases are reported. Of these, 18 patients had clinically normal conjunctivas. Sixteen of them showed no growth, only a few colonies, not enough to justify postponement of the operation. Three showed many colonies, which, under treatment, cleared up, and the operation was done without the development of an infection. The only case in which an infection occurred following the cataract extraction was in a patient who clinically

had a normal conjunctiva, and a culture had not been done previous to the operation.

It would seem advisable to postpone an operation in the presence of six or more colonies of *Staphylococcus haemolyticus* (toxigenic), or two or more of *Streptococcus haemolyticus*, *pneumococcus*, or *Bacillus pyocyaneus*.

We wish to thank Anna C. Riis and Marian C. Shevly for their bacteriologic assistance.

NOTES, CASES, INSTRUMENTS

ANTERIOR MEGALOPHTHALMOS AND ARACHNODACTYLY

A CASE REPORT

W. V. STEPHENSON, M.D.
Toledo, Ohio

CHARACTERISTICS

The average horizontal diameter of the cornea is 11.6 mm., while the vertical diameter measures 10.6 mm.¹ In all cases of anterior megalophthalmos the corneal diameters are enlarged and may even reach 18 mm.; but in addition to the enlarged corneal diameters, there are other signs, according to Vail,² such as: 1. It is hereditary. 2. Always bilateral and limited to the male sex, except in cases of consanguinity. 3. Absence of all signs of glaucoma. 4. Deepening of the anterior chamber. 5. Iridodonesis. 6. Atrophy of the stroma of the iris. 7. Embryotoxin. 8. Dislocated or tremulous lens. 9. Sometimes a melanosis of the cornea. 10. Unusually visible nerve fibers in the cornea. 11. Sharply defined corneoscleral margin.

CASE REPORT

D. D., a white female, aged five months, was seen on the Ophthalmic Service at Cincinnati General Hospital on October 27, 1941. Diagnosis of arachnodactyly had been made at birth, and the patient had been recently readmitted to the hospital for reduction of intussusception. Recovery was uneventful. Until the present admission the patient had never been ill.

Inspection of the eyes revealed a striking enlargement of the cornea, measuring 15 mm. in the horizontal and 14.5 mm. in the vertical diameters. The cornea was transparent, and the limbus sharply demarcated. There was no evidence of em-

bryotoxin. A marked corectopia of the pupils was present, the right pupil appearing displaced nasally and downward. The upper half of the pupils was oval whereas the lower half terminated in an acute angle, much as in the letter V. They measured 2 mm. in the horizontal diameter and 3 mm. in the vertical diameter, and reacted well to light and accommodation. The anterior chamber was very shallow and the irides a pale blue. Examined with a plus 20 lens, the superficial stroma of the iris was seen to be atrophic, with a complete absence of the normal crypts, while the radiating arrangement of the iris fibers was very conspicuous. There was no iridodonesis. The lens was in normal position, the media were clear, and the fundus was seen distinctly with a plus 4 lens. The disc of the right eye was elliptical in shape in the 80° axis, while the left disc was elliptical and in the 110° axis. The choroidal vessels were very apparent, giving the fundus a tessellated appearance.

Slitlamp examination and tonometric measurements could not be made; however, the tactile tension was normal. Transillumination did not reveal the "target reflex" described by Vail.

Physical examination disclosed a thin, white, female baby possessing fine blond hair and a dolichocephalic skull. The chest was somewhat funnel-shaped, but the remarkable finding was the abnormal thinness and length of the long bones of the body (dolichostenomelia), especially of the hands and feet, the latter having the appearance of the limbs of a spider, hence the name arachnodactyly. There was a muscular wasting of the arms, forearms, hands, thighs, legs, and feet. The abdominal muscles did not share this process. There was no kyphosis. There

was a marked flexion deformity of the fingers resembling a "claw hand." The ligaments about the joints of the shoulder, elbow, wrist, hips, knees, and ankles were especially lax. The legs could be bent flat on the back and crossed with no semblance of pain. The external malleoli of the tibia were very prominent. There was no clubbing of the fingers, and nails were normal. However, there was a tiny supernumerary digit on the ulnar side of the hand.

The skull was symmetrical in shape, palate and teeth were normal, and no abnormality of the ears was noted. The lungs and heart were normal as also the abdominal viscera (noted at operation). Neurologic examination was negative.

Radiograms of the hands and feet revealed a marked increase in length out of all proportion to the body height. However, there was no abnormality in the bone structure *per se*. The sella turcica and clinoid processes were normal for this age.

The thyroid and other endocrine glands were apparently normal.

Gross and microscopic examination of the urine was entirely negative and the blood count was normal. The Wassermann test was negative.

Inasmuch as this disease has a familial tendency, an inquiry was made into family history, especially as pertaining to the eyes. The grandparents, as far as could be ascertained, had normal eyes. The parents were not related. Five other children exhibited normal corneas, although the diameters were slightly larger than normal.

THEORIES REGARDING ETIOLOGY

The hereditary and etiologic aspects of this disease have been discussed in great detail by many other authors. I merely wish to stress the theory of gene ex-

change by Rados³ as being more satisfactory in the explanation of the variations found in megalophthalmos. The present paper shortage precludes a discussion of his theory, but with it in mind, one easily sees how conditions such as anterior megalophthalmos can exhibit a megalocornea and atrophy of the iris, or megalocornea and a shallow anterior chamber, or megalocornea and ectopia of the lens, or that there may be megalocornea alone. Any of the aforementioned combinations are possible according to the disturbance in the original gene. The major characteristics enumerated by Vail are not necessary for a diagnosis of megalophthalmos.

Anterior megalophthalmos may be associated with a long, slender body structure as in the case herein described, or with embryologic defects in the skin about the orbit, as in a recent case not published, or associated with polydactyly, syndactyly, and other abnormalities.

There are then many variations to be expected in an anomaly such as anterior megalophthalmos. In my case the anterior chamber was shallow instead of deep, the lenses were not ectopic, and of course there was no iridodonesis, although all of these signs could develop in later life. A better term to describe these variations might then be suggested such as anterior dysophthalmos. Anterior megalophthalmos, megalocornea, persistent pupillary membrane, ectopia lentis (usually transmitted as a dominant characteristic), microphakia, microcornea, and anterior microphthalmos (colobomata* of the iris often seen) could then be classified as variations of anterior dysophthalmos.

* If the mechanical hindrance to the development of the iris is operative at an early stage before the iris has begun to grow forward, a coloboma results; but if it becomes operative after the iris is already partly formed, an ectopia is produced (Duke-Elder, v. 2, p. 1318).

SUMMARY

A case of arachnodactyly associated with anterior megalophthalmos has been presented. Emphasis has been given to the genetic aspects of the disease. It has also been shown that there are many variations of anterior megalophthalmos, which is to be expected, owing to the infinite number of variations of minute

disturbances in the genes. Finally, a term has been suggested, anterior dysophthalmos, which, while not conveying the thought of an enlargement of the anterior segment, does cover all the variations found in this disease as well as others of a related nature.

SUCTION INSTRUMENT FOR CATARACT EXTRACTION*

C. I. THOMAS, M.D.
Cleveland, Ohio

For the removal of cataracts by means of suction, this instrument was devised to provide the following advantages: It is easy to manipulate; the suction power is adequate; and the suction is self-controlled in being automatically cut off when the cap is removed from the lens.

The Dimitry syringe was used to produce the suction, but it was found that the suction power of this instrument could be increased to great advantage.

This instrument displaced a 5-mm. column of water 45 mm. in height, a value increased to 65 mm. by shortening the stem of the piston.

A 6-inch length of firm rubber tubing connects the syringe to the handle by means of adaptors.

The handle having the suction needle is easy to manipulate and was made to correspond in curvature to the Kirby intra-capsular-lens forceps.

In using the instrument the assistant holds the syringe and the suction is applied as directed by the operator.

RETINOSCOPY AT A VARYING DISTANCE

HARRY EGGERS, MAJOR (MC), A.U.S.
Oakland, California

Speed is a desideratum in the preliminary phase of a refraction. The frequent changing of lenses in a trial frame before a patient's eyes during retinoscopy is wearisome and time-consuming. At the conventional distance of one meter the examiner must rise repeatedly from his seat in order to reach the trial frame and change the lens. The use of a vertical bar or frame of spherical lenses is scarcely less troublesome. The patient must be instructed how to hold and move it properly; furthermore, any tilting of the bar will introduce a false astigmatic factor.

The procedure to be described* should eliminate some of the usual changing of lenses. It also should enable the examiner to ascertain rapidly whether or not astigmatism is present, and if so, the approximate amount.

The examiner sits at a distance of about three quarters of a meter from the patient, and, flashing his retinoscope, moves toward the patient and watches for a point of reversal. If the reversal involves all meridians a spherical error, of course, is present, and no appreciable amount of astigmatism should exist. If the reversal occurs in only one meridian, the distance from the patient's eye is measured quickly along a marked tape that is stretched from the patient's eye to the retinoscope. The examiner then moves in still closer until the opposite meridian shows a point of reversal. Again, this distance is measured on the tape. The dioptric value of the difference between the two distances indicates the amount of astigmatism. Following is a detailed explanation and description.

* Very likely this procedure is not original. The author, however, is not aware of its use by anyone else.

The examiner sits at a distance of 75 cm. from the patient. If the eye is hypermetropic and astigmatic a sufficiently strong convex spherical lens is placed in the trial frame before it to bring the first point of reversal (the far point of the first of the two principal meridians that have been made artificially myopic by the convex sphere) to a distance of a little less than 75 cm. from the patient's eye. Usually one or two lens changes will be sufficient to find the right strength for converting the "with" movement of the image of the illuminated retinal area to an "against" movement. If the eye is myopic and astigmatic a sufficiently strong concave sphere is placed before it in order to advance the image of the illuminated retinal spot to a point that is a little less than 75 cm. from the patient's eye. Once the proper lens is in front of the eye the examiner moves in along the marked tape (to be described in the next paragraph), flashing his retinoscope alternately in the horizontal and vertical meridians until a point of reversal is seen in one of the meridians (until the "against" movement of the image changes to a "with" movement). At this point the position of the retinoscope along the tape (the distance from the patient's eye) is noted. The examiner then continues to approach the patient until a reversal occurs in the opposite meridian. Again the position of the retinoscope along the tape is noted. Then, moving slowly backward, the examiner checks his findings by once more observing the positions of the two points of reversal. This time the change will be from a "with" to an "against" movement. Once the proper spherical lens is in place the examiner can perform this whole measurement without leaving his seat by simply bending from the hips first forward slowly and then backward. The difference in the dioptric values of the two distances on the tape indicates the amount of astigmatism that is present.

Ordinary narrow cotton or linen tape may be used. A mark is made near one end. The patient holds the tape against the side of his face so that the mark is in line with the front of his cornea. Various convenient distances are marked off on the tape starting from the mark. The dioptric values of these distances are printed over each mark. The following values represent a suggested series of distances and their designations: at 15.4 cm., 6.5D.; at 16.7 cm., 6D.; at 18.2 cm., 5.5D.; at 20 cm., 5D.; at 22.2 cm., 4.5D.; at 25 cm., 4D.; at 28.6 cm., 3.5D.; at 33.3 cm., 3D.; at 40 cm., 2.5D.; at 50 cm., 2D.; at 66.6 cm., 1.5D.; and at 75 cm., 1.3D. If the examiner holds the retinoscope with the right hand he loosely takes hold of the tape near its middle with his left hand. As soon as a point of reversal is noticed the tape quickly is stretched taut as far as the retinoscope, and mental note is made of the dioptric value of that distance.

The author has found this procedure to be useful in some cases. Its basis is a change of distance rather than the conventional change of lenses. No procedure is universally applicable, and a stereotyped method of refraction cannot be used satisfactorily in all cases.

Oakland Regional Hospital.

EYE FINDINGS IN RHEUMATIC FEVER*

CARL J. RUDOLPH, MAJOR (MC), A.U.S.

In recent years there has been a marked trend to delete rheumatic fever as the basis for eye involvements such as iritis, iridocyclitis, uveitis, choroiditis, episcleritis, scleritis, and the like.

The Quarterly Cumulative Index Medicus shows a marked diminution of

articles describing eye lesions as a complication of rheumatic fever. The Index Catalogue of the Library of the Surgeon General's Office shows a similar trend:

1st series—1880-1895 reference was made to 13 books and 53 periodicals.

2d series—1896-1916, one book and 39 periodicals.

3d series—1917-1932, one periodical.

4th series—1936-1942, no listing of books nor periodicals.

The reason for this trend is undoubtedly due to the more scientific investigation of a patient and improvements in our laboratory technique. Previously, ocular pathology in which difficulty was experienced in determining its cause was relegated to the category of rheumatic fever. Frequently this would provide a "catch all" for syphilis, tuberculosis, gonorrhea, and other diseases that may provide the basis for a joint involvement and the true diagnosis would have eluded the examiner.

This is well illustrated by Fuchs¹ in describing paralysis of the orbicularis muscle. "These are rheumatic paralyses for the most part of which, however, the real cause is not known." Elsewhere in the same volume by Fuchs several eye conditions are described as being due to rheumatism. To mention two of the more vague references: page 197, rheumatism as etiology for scleritis and sclerosing keratitis; page 222, episcleritis rheumatica.

The existence of a doubt as to etiology is well exemplified by Knies² in 1895. "An acute articular rheumatism must be regarded as an infectious disease, although a typical agent of inflammation has not been discovered."

E. V. L. Brown,³ in 1937, calls attention to the fact that rheumatic iritis is not specific.

In 1915, A. E. Davis⁴ stated: "Some of the affections of the eye which have a rheumatic origin are: Iritis, cyclitis, epis-

* This article concerns itself primarily with acute rheumatic fever and not with the chronic arthritides, since these are, in most instances, of an undetermined etiology.

cleritis, scleritis, keratitis, sclero-keratitis, inflammation of Tenon's capsule, muscular paralyses and optic neuritis and even glaucoma have been attributed to it." This gives a concrete example of the numerous disease entities formerly ascribed to rheumatic fever.

The uncertainties of treatment and diagnosis are reflected in the two following quotations: Emil Erroth,⁵ 1932, advises "a change of climate to be of benefit in cases of rheumatic iritis."

F. E. Noboa-Recio,⁶ 1941, suggests X-ray examination of joints to establish the identity or type of joint involvement and also the use of the sedimentation test.

The present trend to minimize rheumatic fever as the cause of ocular disease is the more plausible because the eye complications are thought of as a part of the picture of syphilis, tuberculosis, gonorrhea, and the like, and are classified under that heading, hence the scarcity of literature of recent date captioned rheumatic fever as an etiologic basis for various and sundry eye involvements.

A careful study of the eyes in 105 cases of rheumatic fever at Buckley Field has resulted in essentially no eye findings. This is emphasized by the fact that approximately 200 additional rheumatic-fever cases have been confined to this hospital during the same interval of time—September, 1943, to March, 1944, inclusive—without unusual subjective or objective eye symptomatology. Two additional Army hospitals in this area, Lowry Station Hospital and Fitzsimons General Hospital, likewise report negative findings; the first in 300 cases of rheumatic fever and the second in 50 cases.

The most recent work at this time credits the group-A hemolytic streptococcus as probably being the exciting factor in rheumatic fever. One hundred five cases were selected at random and

were carefully examined as to vision, anterior segment, media, and fundi. The pupil was dilated in all cases to allow access to the extreme periphery of fundus.

The cases were classified under three headings: (1) severity (mild, moderate, severe); (2) stage (early, mid, terminal); (3) eye findings.

Severity:	Stage:		
Mild	12	Early	18
Moderate	40	Mid	40
Severe	53	Terminal	47

These figures would indicate a fairly good cross section of cases. We were anxious to obtain this so that if any ocular pathologic changes were manifested as a transient involvement they should have been discovered in some of the cases examined.

The eye findings were as follows:

- (1) Eyes normal throughout, 94;
- (2) Injection of deep conjunctival vessels, 9;
- (3) Blood in veins dark, 2;
- (4) Vision in no case was impaired as a result of rheumatic fever.

An analogy between joint involvement and teno-synovitis was considered. A purpling of the deeper conjunctival vessels was found in nine cases; however, the classical symptoms of a teno-synovitis were nonexistent.

Fields: Fields were taken in 20 cases of recurrent rheumatic fever, for it is our impression that these cases would be the more likely to show a field defect provided there was at any time during the course of the disease an involvement of the optic pathway. No field defect was found. An isopter of 2/1,000 was employed.

These results were in marked contrast to the finding of Pillat as quoted by Lowenstein⁷ "Foci similar to the foci in miliary tuberculosis can be found in 61% of the cases of acute rheumatic fever by ophthalmoscopy."

An interesting observation made in regard to the patients who received massive doses of salicylates was that approximately 50 percent of them observed visual phenomena described as lights passing across their field of vision. This was noted to a lesser degree in those receiving penicillin. The phenomena was also markedly reduced in the controls who received soda bicarbonate and/or bed rest. The intensity of light was described by different individuals as varying in intensity from silver spots to the appearance of a roman candle.

In approximately 20 percent of the cases there was evidence of increased rapidity of the fatigue time of accommodation. This was noticed mostly in those who were hyperopic to a moderate degree and who were not conscious of asthenopia before contracting rheumatic fever. Chief complaint was "tiring of the eyes" after reading for a short time. Frequently a general debilitating illness will result in this finding.

In conclusion, it is our impression that the group-A hemolytic streptococcus, presumably causing rheumatic fever, may involve the eyes. However, we are convinced that rheumatic fever has in the past been accredited as the etiologic basis for eye conditions for which it was not responsible. This confusion is easily understood, as the rheumatic involvement with hemolytic streptococcus is far different from the ordinary reaction to this organ-

ism, the former being on an allergic basis.

In a careful study of 105 cases of rheumatic fever which was taken as a typical cross section of 650 cases in all, together with a review of literature, we are convinced that there is no ocular pathologic change pathognomonic of rheumatic fever.

"Penicillin and the sulfa preparations have to date had no definite therapeutic value in the treatment of rheumatic fever,"⁸ therefore it should not be of benefit in treating an ocular complication of rheumatic fever.

Grams⁹ and I concur with Lowenstein¹ in the impression that rheumatic fever is an allergic manifestation pathologically characterized by fibrinoid necrosis of collagenous ground substances followed by a cellular response known as the Aschoff body.

The credit for the last two conclusions should be given to the departments, mentioned in references, which are also engaged in research work on rheumatic fever under the auspices of Major General David N. W. Grant, Surgeon for the Army Air Forces, and his staff.

202d General Hospital Unit.

Since the time this paper was written, I have examined approximately 45 more cases of rheumatic fever. Three patients had transient scotomas, which entirely disappeared within 30 to 90 minutes. One of these was due to an angiospasm of a branch of the central retinal artery; the other two to angiospasm of an artery in the occipital cortex.

SOCIETY PROCEEDINGS

EDITED BY DONALD J. LYLE

ROYAL SOCIETY OF MEDICINE

SECTION OF OPHTHALMOLOGY

November 12, 1943

MR. FRANK A. JULER, *president*

Abstracted by permission from the Proceedings of the Royal Society of Medicine (Section of Ophthalmology), 1943, volume 37, no. 2, sectional page 7.

INTRAOCULAR FOREIGN BODY

MR. J. W. E. CORY presented an engineer, aged 37 years, who was seen on October 12, 1943. He gave a history of having got something in his right eye three days previously.

A large metallic foreign body was seen lying in, or just posterior to, the posterior capsule of the lens. There was a small entrance wound at the 2-o'clock position, 2 mm. from the limbus, but there was no visible injury to the iris.

The vision was R.E. 6/60 (previous to accident 6/36 improved to 6/9) and L.E. 6/6. The fragment, which was part of a brass cotter pin, showed indistinctly in the X-ray picture and was nonmagnetic.

There seemed to be very little reaction after five weeks and it was deemed advisable not to operate unless a cataract developed.

FLOCCULI

MR. R. A. D. CRAWFORD presented a soldier, aged 25 years, who had had no previous trouble with his vision until he complained of blurring of the vision of the left eye in strong sunlight. He had flocculi of both irides, larger in the left eye than in the right, and in the left eye there had formed an anterior attachment to the back of the cornea. No reference to this condition, last named, could be found in the literature. The condition apparently resulted from a failure of clos-

ing and cystic dilatations of the marginal sinus.

Discussion. Mr. F. A. Juler said that he had never seen an attachment to the cornea of this kind. The common "grape-seed bodies" protruded into the pupil, but he had not seen them hanging in the anterior chamber.

Mr. A. Greeves said that it seemed likely to him that the mass was not actually attached to, but merely in contact with, the posterior corneal surface against which it was flattened on account of its bulk.

EPIBULBAR DERMOID WITH RUPTURE OF CYST CONTENTS INTO ANTERIOR CHAMBER

DR. VICTOR PURVIS reported the case of a child, aged one year and four months, who was brought to Moorfields Hospital one year ago with a history of a swelling on the right eye since birth. Recently a sudden increase in the size of the swelling had been evident.

On examination it had all the appearances of an epibulbar dermoid, but there was an amount of white flocculent material in close proximity to it in the anterior chamber. It was considered that this material was the contents of a ruptured dermoid cyst. During the next few months the eye became irritated from time to time and the flocculent material became absorbed, drawing down the pupil in the process.

Two months ago another mass of material suddenly appeared in the anterior chamber near to the cyst, as if the latter had ruptured once more. It was proposed to wash out the anterior chamber to ascertain the nature of the material and enable a correct diagnosis to be made. If the tumor proves to be a dermoid it is unique, for these are rarely cystic at this site and are not known to rupture into

the anterior chamber in the way described. On the other hand it might have been an implantation cyst in spite of the fact that there was no history of injury.

THE INCIDENCE AND TREATMENT OF OPHTHALMIA NEONATORUM

PROF. ARNOLD SORSBY said that ophthalmia neonatorum has been a notifiable disease in England and Wales since 1914, and has shown some decline in incidence. There is, however, considerable variation in the rate of notification in different parts of the country, pointing to different conceptions as to what constitutes notifiable ophthalmia neonatorum. Replies to a questionnaire sent to lying-in centers indicate a rate of gonococcal ophthalmia of 0.8 per 1,000 births. On this basis there are annually about 500 cases of this type of ophthalmia neonatorum and a total of about 2,000 cases of all types throughout the country.

The annual returns of the Ministry of Health indicate a steady decline in the incidence of impaired vision and blindness from ophthalmia neonatorum.

Antenatal care is of prime importance, as is shown by excellent results in eliminating ophthalmia neonatorum at such centers as Sheffield Street Hospital for mothers suffering from venereal disease. Prophylactic drops instilled into the eyes of babies at birth are no absolute safeguard against gonococcal ophthalmia, as the occurrence of 98 cases in 119,075 births given in the returns of the questionnaire show. On the basis of these returns the incidence of gonococcal ophthalmia is 0.9 per 1,000 births when silver nitrate is used as a prophylactic, and 0.7 per 1,000 births when other preparations are used (generally argyrol).

The immense advance marked by the sulfonamides in the treatment of ophthalmia neonatorum of all types is shown by the fact that in 500 cases treated at White Oak Hospital during January,

1940, to October, 1943, no less than 72.2 percent cures were effected within eight days (against 15.2 percent of cases treated by the classical method).

Discussion. Dr. Letitia Fairfield said with regard to the question of notification, that London was the pioneer in collecting cases of ophthalmia neonatorum into a specialized hospital (Saint Margaret's now evacuated to White Oak). The London notification rate was only about 9 per 1,000 as against the 60 per 1,000 of Birmingham, but the results were very similar.

She said that the prophylaxis used for infants in the London County Council wards was very much like that described by Professor Sorsby, and the variety of drugs employed seemed to matter little. The figures showed that antenatal care seemed the main preventive factor, but a certain number of cases did slip through in spite of very careful antenatal work.

Prof. Chassar Moir said that a slight inflammation of the eyes was very common in the first week of life. Cases of "sticky eye" were often not notified, and discrepancies in statistics could be largely explained by this fact. As prophylaxis against gonococcal ophthalmia, silver nitrate has stood the test of time, but it was also true that silver-nitrate solution was irritating and frequently produced a chemical conjunctivitis of its own. His belief was strengthened by the fact that after the use of a 2-percent solution of silver nitrate instead of the usual 1-percent, cases of inflammation were much commoner and more severe. The possibility of serious harm resulting from the reckless repeated use of silver nitrate, the other name of which is lunar caustic, should be realized. Better methods of treatment were now available.

Mr. Frederick Ridley said that his experience had also been that the use of silver nitrate did undoubtedly lead to a large incidence of "sticky eyes." The

treatment of such eyes by silver-nitrate drops was definitely harmful. He believed it was dangerous to use even a 1-percent solution of silver nitrate upon a baby's cornea which was already ulcerating, and he thought it should be barred. The acidity of a 1-percent solution of silver nitrate kept in a tightly stoppered bottle had reached the value of pH2. The concentration also continually increased by evaporation, and he had seen silver-nitrate crystals formed in a dropper bottle; such drops were capable of blinding a baby.

Argyrol was a safe and even more effective prophylactic than silver nitrate. It did not change spontaneously on keeping; even if it became concentrated by evaporation, it did not become harmful. He would strongly advocate that argyrol be used in the place of silver nitrate as a routine prophylactic.

Professor Sorsby, in closing, said it was futile to rely upon one solitary measure for the elimination of ophthalmia neonatorum. In the whole range of public health there was no procedure which would rely on one drop of an antiseptic to prevent the development of infection in people who had been exposed to it. Antenatal care was extraordinarily important as the figures had shown.

In very many institutions silver nitrate was used as a standard method. It had been used in millions of births so that it could not be so desperately dangerous as some people believed. That did not mean, however, that there were no better drugs. The figures obtained from lying-in hospitals possibly showed argyrol to be superior to silver nitrate, but the series was too small from which to judge.

RUPTURE OF RETINAL CYST CAUSING RETINAL DETACHMENT

MAJOR C. DEE SHAPLAND (RAMC) presented J. S., a soldier, aged 28 years, who was sent to the hospital on Septem-

ber 20, 1943, because of failing vision in the right eye, noticed for the previous six weeks. On August 2, 1943, the day before he noticed that the vision in the right eye was misty, he had felt a sudden sharp shooting pain lasting about two or three minutes in the region of the right temple, and felt giddy and faint.

On examination, on September 20th, the right eye was white and there were no keratitic precipitates. The pupil was active and the tension was normal. A flat detachment of the retina was present temporally, extending from the 6:30- to the 11-o'clock position. From the 7- to the 9- o'clock position there was a prominent thin-walled retinal cyst, with ragged dialysis from 7:30- to the 9-o'clock position. The interesting feature was a linear band of retinochoroidal pigmentary disturbance delimiting the periphery of the cyst above and below. This disturbance was the type usually seen at the high-water mark of static detachments of long standing. Therefore the cyst was old.

It had evidently ruptured at its peripheral attachment at or just behind the ora serrata, and the delimiting band of choroidoretinal adhesions had given way over the nasal part of the cyst and caused a spreading detachment of the retina over the temporal half of the fundus. The macula was involved in the detachment, and central vision was reduced to 3/60. The visual field was contracted nasally.

Operation was performed on September 24, 1943. The external rectus was detached and a barrage of surface diathermy applications was placed around the periphery of the scleral-surface marking of the cyst. One needle puncture was made over the center of the cyst and another at the 6:30-o'clock position, 12 mm. from the limbus. The patient was kept in bed in the Fowler position with both eyes padded for two weeks and was allowed up for an hour on the fifteenth

day. The retinal detachment went back and the cyst was smaller and outlined by a zone of diathermy reactions. The contraction of the diathermy punctures had pulled down the wall of the cyst and caused it to shrink. The dialysis was still clearly visible and open. The retina was in place. The central vision was 6/24, partly. The visual field was full except for a defect on the nasal side corresponding to the cyst and diathermy reactions.

This case was interesting in that a retinal dialysis, as had long been suspected, could definitely be produced by the rupture of a cyst and that little or no trauma caused its rupture. In this patient the periphery of the cyst tended to be sealed off by a zone of spontaneously formed retinochoroidal adhesions, and a portion of these gave way on the formation of the dialysis and so caused a spreading detachment of the retina.

Discussion. Mr. C. B. Goulden said that the connection between retinal cyst and disinsertion had long been suspected, and some suggestive findings by Weve of Utrecht gave support to this possibility. He had found that the retroretinal fluid removed in cases of disinsertion had similar enzymes to those found in the fluid from a retinal cyst. He believed that in cases of retinal cyst operation should be undertaken before they gave rise to disinsertion, as they were much more easily managed.

Dr. T. H. Whittington said that he recalled several cases of retinal cysts. One was in a man who came for a detached retina due to a disinsertion, and in making the routine examination of his eyes an unruptured peripheral cyst was found at exactly the corresponding spot in the other eye. The second patient was a nurse who had a disinsertion which looked just like a ruptured cyst, and there was an unruptured cyst of similar appearance close by. Both cases were successfully treated.

COLORADO OPHTHALMOLOGICAL SOCIETY

DR. C. A. RINGLE, *president*

CARCINOMA OF THE CHOROID

DR. F. NELSON presented the case of Mrs. B. G., a white woman aged 65 years, who was first seen September 8, 1943. She complained that two days previously a brown cloud had appeared before her left eye in the lower part of the visual field.

The fundus of the left eye showed a very flat disclike elevation about 10 disc diameters wide, and of not quite that height, located above the macular region. The elevated area slanted very gradually to the normal level of the retina. The elevation at the highest spot was about 6 diopters, corresponding to about 1.5 mm. The color of the detached area was slightly yellowish-pink. Both eyes had a refractive error of about 5 diopters. The corrected vision was R.E. 5/5, L.E. 5/8 partially. The visual field of the left eye showed a relative scotoma corresponding to the detached area.

The history was somewhat difficult to establish, since the patient was a Christian Scientist and was reluctant to reveal exact data of previous illnesses. The right breast had been removed in August, 1938, but the patient had noticed a lump in that breast since 1935 or 1936. She had refused surgery at that time. She complained of loss of weight and showed signs of vitamin-B deficiency. There was irregular pigmentation on the dorsum of both hands and the tongue showed changes which were characteristic of pellagra.

The patient was admitted to Glockner Hospital, and a diagnosis of detachment of the retina of the left eye due to possible metastatic malignancy in the choroid

was made. During the period of observation the detached area seemed to flatten and the positive scotoma became less noticeable. The patient became more and more dyspneic and cyanotic. An X-ray picture of the chest showed thick shadows over the whole left lung field, indicating invasion of the tumor into that lung. During the last week of her life she became more disoriented and had hallucinations. The patient died on October 11, 1943.

Autopsy showed generalized carcinomatosis. The brain was free of metastases but showed a number of minute cortical hemorrhages. The left lung was almost totally involved in tumor masses invading numerous bronchi. The right lung was affected to a minor degree. The primary tumor of the right breast had not invaded the chest wall. A number of coin-shaped cancerous lesions were found in the liver, particularly on the convexity and in the lobus quadratus. The heart was not enlarged but showed a number of flat tumor masses in front of the conus arteriosus. The tumor had invaded the heart muscle deep into the interventricular septum. A very advanced sclerosis of the coronary arteries apparently had prevented the tumor from invading the arteries themselves, so that in this case the sclerosis had given the heart a certain amount of protection. The left eye was enucleated, *post mortem*, and showed a flat carcinoma of the choroid above the posterior pole in about the same extension as the ophthalmoscope had revealed. Cross sections through the stump of the optic nerve showed a tiny strand of accumulated tumor cells in the outer layer of the nerve sheath, probably located in a small lymph vessel. It is possible that the metastases in the choroid spread from this strand.

Conclusions. A breast carcinoma was removed probably three years after the

beginning of the primary tumor. Extensive metastases occurred five years after the first operation and about eight years after the beginning of the primary tumor. The first subjective and objective manifestation of generalized carcinomatosis was in the choroid.

MALIGNANT MELANOMA OF THE RIGHT CHOROID

DR. F. NELSON presented the case of Mrs. A. A. F., aged 54 years, who was first seen on August 22, 1938. She complained of continuous flashes in the right eye which had been present for about 18 months. A diagnosis of focal infection had been made.

The eyes were externally normal. The corrected vision was R.E. 5/5, partially; L.E. 5/4. A large detachment of the retina was found in the nasal section of the right eye. The detachment was hemispherical in shape and showed no fluctuation nor folds. The color of the detachment was slate-gray with some darker spots shining through the retina. Transillumination revealed complete darkness in the detached area, indicating a tumor formation behind the detachment. The intraocular pressure was 18 mm. Hg (Schiotz) in both eyes. The visual field showed a large peripheral scotoma corresponding to the detached retinal area. A diagnosis of malignant melanoma of the choroid of the right eye was made. Enucleation was advised and performed the next day.

Histologic examination revealed a malignant melanoma of the choroid mushrooming into the intraocular space at the nasal side of the globe. In some sections wandering of tumor masses along one posterior ciliary nerve was observed. This perforation could not be seen macroscopically. Pigment cells were more abundant in the intrascleral tumor.

The patient was seen once a year, the

last time on October 13, 1942. At that time no local recurrence was found and there was no evidence of metastasis to any other part of the body. The patient was warned to watch for liver or gall-bladder trouble. During the summer of 1943 the patient developed some abdominal distress and reported loss of weight. A surgeon detected an enlargement of the liver and did an exploratory laparotomy on July 19, 1943, and found definite malignancy of the liver. The patient died on October 8, 1943.

Metastasis to the liver is more frequent in cases of malignant melanomata of the uveal tract. In this case almost seven years elapsed between the first ocular symptoms and the patient's death. Abdominal operations in such cases are usually unnecessary and contraindicated. Specimens of the tumor were shown microscopically.

BILATERAL OCULAR INJURY

DR. V. H. BROBECK presented the case of M.G., aged 14 years, who was injured by the explosion of a dynamite cap on June 19, 1940. When he was first seen, one hour following the injury, the distal phalanx of the thumb, middle finger, and ring finger of the right hand were destroyed. The upper two-thirds of his face was the site of countless small perforating abrasions and punctured lesions of the skin and eyelids.

The anterior chamber of the right eye showed considerable hyphemia. Two small lesions, one on the cornea and one on the episcleral region below the level of the insertion of the right internal rectus muscle, were quite probably locations of the perforating foreign bodies. After clearing occurred in this eye, a fairly large glistening foreign body was observed in the lower nasal anterior segment. Beneath it was a large area of chorioretinitic damage.

In the left eye, the lens soon became cataractous following its perforation by a metallic fragment. After a period of six weeks the synechiae in this eye were freed by a keratome incision at the 3-o'clock position, the lens was "puddled" and the anterior chamber irrigated with saline. This resulted in the recovery of a brass foreign body, 0.5 by 1 mm. in size.

Two years after the injury, the right eye, still containing the copper in the vitreous, was quiet, and the vision was 0.8. It had never showed signs of irritation since the first inflammatory reaction subsided, but the vision finally was reduced to light perception.

The vision of the aphakic left eye was 0.5 with +16.00D. sph. \ominus -4.50D. cyl. ax. 135°; +3.00D. sph. added for near vision.

Many consultants in the Middle West agreed to leave the right eye unmolested under a régime of frequent inspection. The left eye had just recovered from an attack of iridocyclitis.

QUESTIONABLE DETACHMENT OF THE RETINA

DR. E. N. NEEPER presented Mrs. A. C., who was first seen in August, 1927, at which time she was 26 years old and a patient in a tuberculosis sanatorium. Headaches and blurring of vision were relieved by correction of refractive error. Ophthalmoscopic examination showed a small inflamed area just below and slightly to the temporal side of the disc in the right eye, and an old pigmented area, 1.5 mm. in size, below the disc in the left eye. The area was surrounded by moderate hyperemia.

At various times during the following five years choroidal tubercles in different stages were seen in both eyes, each such area finally healing with only slight or no perceptible damage. Old tuberculin, in his opinion, proved to be the treatment of

choice. A period of 10 years elapsed without any complaints referable to the eyes or general health. Since November 12, 1943, however, the patient had complained of floating opacities and flashes of light, day or night, on quick head movements. The vision, L.E., was 20/15-2. Examination of the visual field showed a moderate scotoma above and to the temporal side. Copper-tinted linear opacities were present in the vitreous. No detachment folds nor prominences could be seen. There was, however, slight pallor below the disc and macula. Visual field, taken on November 18th, revealed a 20-degree, deep, irregular, crescent-shaped blind area 15 degrees below the macula.

This case was presented as a probable simple, flat, retinal detachment. The diagnosis was based largely on the presence of the blind area and the photopsia. The absence of any central scotoma, headache, and pain in the orbit on eye movement or pressure ruled out retrobulbar neuritis.

Discussion. Dr. George Stine suggested as a possible diagnosis a low-grade uveitis, but thought that the case required further study.

HERPES ZOSTER OPHTHALMICUS

Dr. E. N. NEEPER presented Mr. J. A., aged 65 years. He gave a history of severe influenza in January, 1943, which left him in poor health. In March, 1943, he complained of much pain in and above the left eye. A diagnosis of neuralgia was made by his physician. The use of hot compresses was instituted, but it was thought that the hot packs scalded the skin and that a skin infection followed on the forehead. During the four months that followed he suffered much pain. The patient was seen for the first time by Dr. Neeper on July 13th, when the diagnosis was obviously herpes. Posterior synechia was present. The ciliary ring was greatly injected. The cornea stained

throughout. The vision, L.E., was ability to see light.

When last seen only one narrow tongue of the synechia remained. Occasional corneal staining occurred. There was intermittent slight ciliary injection, and while the patient was conscious of all of the involved area most of the time, paroxysms were gradually becoming less frequent. The vision at this time was 20/120 owing to the lens and corneal haziness. As the toxins are gradually eliminated it is hoped that useful vision will be restored.

Medication consisted of atropine, paradrine, phemerol, sulphonamides, and dionin.

Discussion. Dr. J. W. Lamme reported good results in the treatment of this disease from the use of sodium iodide, snake venom, and viosterol.

W. A. Ohmart,

SAINT LOUIS OPHTHALMIC SOCIETY

November 26, 1943

Dr. CARL BEISBARTH, *président*

THE USE OF DORYL IN GLAUCOMA

Dr. J. F. HARDESTY presented a paper on this subject which has been published in this Journal (1944, v. 27, June, p. 625).

Discussion. Dr. John Green said that his experiences with doryl coincided closely with those of Dr. Hardesty. He told of a complicated case which he had seen with Dr. Carl Beisbarth at the Saint Louis County Hospital. The patient had absolute glaucoma in one eye and was having an acute attack of glaucoma in the other eye. At the time of admission to the Hospital the vision was reduced to perception of hand movements and shortly thereafter to ability to see light. An iridectomy was done on the better

eye with beneficial effect that lasted about one month. Following that a corneoscleral trephining operation was performed by Dr. Beisbarth, using a 3-mm. trephine. After this operation a normal tension was maintained for at least a year, following which the patient developed a uveitis, with recurrence of the increased tension. After treatment at De Paul Hospital with suprarenin bitartrate locally, general medication, and the removal of several infected teeth, the tension was reduced but did not return to normal. Several months later two cyclo-diathermy operations were performed, resulting in a moderate reduction of tension and the maintenance of vision of 20/60. Pilocarpine and eserine apparently had no effect on the tension. Doryl was finally used and caused a marked lowering of the tension within a short period of time. A tension of 40 mm. Hg (Schiøtz) could be reduced to 20 mm. Hg in an hour after instillation. There was no appreciable effect on the pupil.

Dr. William H. Luedde reemphasized some of the things Dr. Hardesty had discussed. He said that doryl does seem to offer some real advantages. In his experience he had had the greatest satisfaction from the use of doryl in cases of postcataract glaucoma, in which cases it usually seemed dependable. He had had some patients who were sensitive to doryl and who exhibited marked sweating and discomfort following its use.

Major James Allen (MC), by invitation, said that in the past 18 months his experience with glaucoma had been limited to two cases, for glaucoma is not encountered very often in the Army. He said that doryl has been used for a number of years and it has been found to be somewhat unreliable. It is not readily absorbed through the cornea. It may be, however, that if something could be done to the cornea to increase the penetration of doryl through it, the effect

might be better. In the early experimental work on rabbits Oppenheim abraided the cornea and got uniform action. He began to use a solution of 1:3,500 zephiran containing doryl. Repeated use of doryl in this concentration of zephiran often leads to eventual denudation of the epithelium of the cornea. In one early case where it was used four or five times a day for about one month the patient's eye developed a superficial keratitis and beginning vascularization of the cornea. Reducing the concentration of zephiran to 1:5,000 in this case cleared the cornea of the superficial keratitis but the vascularization continued. The patient had no loss in vision, however. It is, therefore, important to prescribe doryl in weak solutions of zephiran. It is not felt that doryl is the final answer to the problem. It has been found quite effective in cases following cataract extraction, but in a great many cases the use of doryl will not prevent a secondary operation.

Dr. Hardesty, in closing, agreed that doryl seemed more effective in glaucoma following cataract extraction than in other types of glaucoma and that unfortunately it is not a general panacea for glaucoma. It does, however, have a real place in the treatment of glaucoma that is not controlled either by the ordinary miotic or by operation, and thus is a real addition in the methods available for treating glaucoma.

THE RESULTS OF ORTHOPTIC TRAINING AT THE WASHINGTON UNIVERSITY EYE CLINIC

DR. JAMES H. BRYAN reviewed the results obtained by orthoptic training on strabismic patients at the Washington University Eye Clinic in the 15 months between May, 1942, and September, 1943, while the orthoptic technician, Miss Anita Steltzer, was available to the Clinic. In that period of time 125 different patients were seen in the Orthoptic Clinic, exam-

ined, their conditions diagnosed, and the future care of their strabismus recommended. Twenty-seven members of this group did enough work with the technicians to make it worth while considering them in this survey. These patients were analyzed and compared with the somewhat similar group that had been seen in the Clinic two years previously and treated with all the various means to correct strabismus with the exception of the work on the machines. It was found that with the exercises: (1) The angle of deviation was not affected in the great majority of cases by the exercises. (2) In the 11 cases of abnormal retinal correspondence 3 patients were cured of the condition; 2 had the angle of anomaly reduced to almost zero, although still somewhat variable; and 6 showed no improvement, although 3 of these 6 should not be considered because they had had less than 10 sessions each. (3) The degree of fusion was improved from no fusion at all to first-degree fusion in one case, and to second-degree fusion in eight cases. Four patients who had no or little fusion ability did not improve in degree. (4) The amplitude of fusion was increased by an average of 24^{Δ} in six of the nine cases of exotropia. In nine cases of esotropia the range of fusion increased an average of 21^{Δ} . Nine others were not improved. It was concluded that orthoptic exercises were of definite value and should be included along with the other methods available in order properly to treat cases of strabismus.

Discussion. Dr. Benjamin Milder, by invitation, said that it is quite generally agreed that the goal of orthoptic training, together with all other measures in the treatment of strabismus, is the establishment of comfortable binocular vision. To achieve this goal, the orthoptic program pursues somewhat the following sequence: (1) refraction; (2) occlusion,

for amblyopia ex anopsia; (3) if anomalous retinal correspondence exists, it must be broken up, and normal regional point-to-point relationship established; (4) suppression must be overcome, if it exists; (5) then, with the ability to superimpose images, amplitude of fusion is developed; (6) stereopsis is stimulated; and (7) the capacity for the eyes to function, with fusion and stereopsis, under normal conditions of use, must be developed.

The chief stumbling blocks, he believed, are the above-mentioned numbers 3 and 7. He cited references which showed the achievements realized by others in overcoming the obstacles (Hitz, J., *Amer. Jour. Ophth.*, 1941, v. 24, p. 1017; Berens, C., Elliott, A. J., and Sobacke, L., *Amer. Jour. Ophth.*, 1941, v. 24, p. 1418).

In comparing the report by Dr. Bryan with those of Dr. Hitz and Drs. Berens and Elliott and Miss Sobacke the following points should be considered: (1) the newness of the program at this institution; (2) the small number of cases followed; and (3) the inclusion of some cases which, in retrospect, may have been eliminated as candidates for orthoptic training before they began. In this connection, care must be taken to exclude patients with stubborn amblyopia, low I.Q., marked anisometropia, innervational anomalies (such as alternating hyperphoria), and fixed abnormal retinal correspondence (as evidenced by no signs of improvement in the first 10 treatments).

Perhaps there will be a time when an orthoptician can supervise daily orthoptic training at the grade schools, using Board of Education equipment, during the "orthoptic" period of the daily school routine.

James T. Bryan,
Secretary.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to Dr. Lawrence T. Post, 640 South Kingshighway, Saint Louis 10, Missouri; Society Proceedings to Dr. Donald J. Lyle, 904 Carew Tower, Cincinnati 2, Ohio. Manuscripts should be original copies, typed in double space, with wide margins.

Exchange copies of medical journals should be sent to Dr. William H. Crisp, 530 Metropolitan Building, Denver, Colorado.

Subscriptions, applications for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the Manuscript Editor, Miss Emma S. Buss, 5428 Delmar Boulevard, Saint Louis 12, Missouri. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Alhnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

DEFINITIVE CARE OF THE WAR BLINDED

According to the present plan war-blinded soldiers are sent to one of two hospitals on our east and west seaboard, respectively. They are kept in these hospitals until their wounds have healed and no further medical care is needed, at which time they are sent to Old Farms Convalescent Hospital in Avon, Connecticut, for 16 weeks of careful examination, to determine their capacities for further education or occupation. Here they are also aided in making their individual adjustment to the world of blindness which they have entered. An important item is in the education of their families, who must be taught not to be overly sympathetic, but to have an encouraging yet realistic attitude.

After their discharge from Old Farms, about which time their pension begins and their discharge from the Army takes place, they are released to the Veterans Administration, which organization has the responsibility for their further care, and, incidentally, of distributing their pension to them. The first two phases of the handling of these blinded veterans is being admirably carried out. But the phase of initiating the life-long care that should follow the preliminary work is not being so satisfactorily administered. Quite obviously it is extremely difficult because the soldier is on his own, with money in his pocket, probably in most cases more than he has ever had before, and he wants primarily to get home and forget about the war and the Army. His family also think that his future happiness will be

best served at home where they and his acquaintances can comfort him and possibly help him spend his Army pension.

Our country is justly generous to these men, allowing them \$190 per month for life. It is regrettable, however, that there seems to be a tendency to consider that the payment of this allotment is all that need be done and that the man may safely be left to shift for himself, trusting that local organizations for the blind, if any, will interest themselves in his case and give him aid and counsel.

It is understandable that the care of from 500 to 1,000 blinded veterans may seem a very minor matter for an organization that must help an enormous number of veterans handicapped in other ways because of their service in the Armed Forces. However, every single disabled veteran is deserving of the best possible care that can be given him, and this principle should apply to the blind perhaps even more fully than to any other type of war-handicapped, because their incapacity is probably the most difficult for which to make adjustments and certainly is one that is most likely to prevent those afflicted from resuming a normal and happy life.

Blindness constitutes perhaps the greatest change in the physical being, and certainly in the viewpoint, that occurs to any of these soldiers. It, therefore, behooves us to see to it that no stone is left unturned in following through with each of these men to make sure that every chance is being given him. An able director in the Veterans Administration whose only concern is the care of war-blinded is a first requirement. This director should be personally familiar with every one of the war-blinded and upon his release from Old Farms should know exactly where each man is going and what he plans to do. A card-index system should be maintained for these individuals, the local blind agencies contacted, and definite plans made for the occupa-

tion of the soldier or his further training if that is necessary. Every bit of red tape should be scrapped and the most direct methods possible employed.

In England this is done very satisfactorily by an essentially private agency known as St. Dunstan's, which acts in full coöperation with the government. For such a duty a private agency is probably not so desirable as is a governmental one. The care of the war-blinded is a national obligation and has been recognized as such by our government when it assigned the definitive care of these soldiers to the Veterans service. This service in all fairness should accept the assignment as an important mandate and should attempt to carry it out in some such manner as is done in England by St. Dunstan's. Whether the idea of a central institute which may serve as a home on occasion for these boys is necessary may be disputed, although the advantage of such a center as a stimulus to the blinded and to the Veterans organization itself cannot be denied. This would be valuable in permitting the blind soldiers to keep in touch with one another and to the organization in maintaining a close relationship with the blinded. But whether or not the central institute is adopted as a part of the program, at least a most careful, intelligent, and continuous follow-up throughout the life of the individual is his due and should be undertaken.

It is natural, perhaps, for ophthalmologists to regard the care of the blinded as quite apart from their own activities because the objective of the ophthalmologists' training has been the restoration and preservation of vision. Few of them have had intimate contacts with the blind or have studied their problems closely. Even so, they must not ignore their obligation since ophthalmologists are held responsible by the public for the care of these unfortunates who have given so much to make life safe and comfortable for them and their children. It behooves

every eye physician definitely to concern himself in the future of these war-blinded, nationally and locally. Eye societies should try to find out when the newly blinded return to their communities and might well appoint committees whose task it would be to keep in touch with these men and make sure that they are not forgotten and that the Veterans organization is doing all that can be done for those thus handicapped in their communities.

Lawrence T. Post.

LOS ANGELES STUDY CLUB

The leaders in the organization known as the Los Angeles Research Study Club are emphatic in attributing to Edward Jackson the inspiration for the creation of this most successful adventure in post-graduate education.

Prior to 1928, Jackson, enthusiastic over the success of the Colorado summer course in ophthalmology and otolaryngology, in whose development he had been the prime mover, suggested to some of his West Coast colleagues that they should establish a similar course under the favorable climatic conditions existing in the winters of Southern California.

At the invitation of Doctors Ray Irvine and M. J. Weymann, Jackson presented in Los Angeles, in January, 1928, a series of lectures on physiologic optics. The following year the ear, nose, and throat surgeons of California organized a short course in those specialties. Then, after a lapse of two years, Dr. Bernard Samuels gave at Los Angeles a midwinter course in the pathology of the eye.

For this course on pathology the "Los Angeles Research Study Club" was formally incorporated, and a combined two-weeks' course in ophthalmology and otolaryngology has been given every winter since then, with the coöperation of teachers from other parts of the United States as well as from abroad.

This year's attendance, including somewhere near one hundred medical guests from the Armed Forces, amounted to approximately four hundred. There was naturally a large attendance from the State of California, but, in all, twenty-seven states were represented, in the north, the south, the middle west, and the Atlantic seaboard.

It has been the custom to place most of the eye work of the Los Angeles course in the first week, and most of the ear, nose, and throat work in the second week. This year the eye events came to a close on Tuesday, January thirtieth. Decision will be made later as to whether in subsequent courses the individual weeks shall be separately allotted to the eye and to otolaryngology, respectively. Many of those present at the final eye luncheon expressed themselves in favor of this procedure.

In view of a recent Government pronouncement or request as to the holding of conventions during the remainder of the war, a conclusion as to whether the Los Angeles Research Study Club shall gather next winter will be reached later.

There can be no question that these meetings, diligently attended, with much use of notebooks, by a large body of specialists furnish a great stimulus to the better practice of ophthalmology and otolaryngology. Physicians who, in the absence of many colleagues overseas, are carrying an extremely heavy load of professional work and responsibility are in need not only of the stimulus afforded by such educational courses, but also of the brief period of relaxation from the daily grind. It is not easy for some of us to understand why there is any lesser degree of justification for travel applied to these purposes among overworked physicians and surgeons than for many other phases of the travel which, quite apart from military necessity, so constantly congests our rail and bus lines.

W. H. Crisp.

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

MacDonald, A. E. Boeck's sarcoid of retina—miliary form. *Trans. Amer. Ophth. Soc.*, 1943, v. 41, pp. 200-203.

Prompted by the findings in a case of reticular-cell sarcoma of both eyes, the author reviews his cases of "non-caseating tubercle of the retina" and reports what he regards as a true case of Boeck's sarcoid in miliary form. A woman aged sixty years gave a history of recurrent iritis in the right eye. The eye was observed for two years and was finally enucleated after severe pain. Clinically the iris showed a grayish mass, 5 mm. in diameter, with blood vessels leading to it. Posterior synechias were present. The left eye also had recurrent attacks of iritis with alternate vision limited to large objects. The original pathologic diagnosis of the right eye was sarcoma, but a review of the slide established a diagnosis of Boeck's sarcoid of the retina, by the finding of several masses of miliary sarcoid scattered through-

out the retina. (3 photomicrographs.)

RETINA AND VITREOUS

Benkwith, K. B. Early ophthalmic findings in a case of spontaneous subarachnoid hemorrhage of the brain. United States Naval Med. Bull., 1944, v. 43, Sept., p. 535.

A 33-year-old enlisted man became unconscious while he was complaining of headache, dizziness, and sudden ringing in the ears. The fundus of the right eye showed generalized attenuation of the retinal arterioles with very definite foci of spasm. The retinal veins were greatly distended and showed no arteriovenous constriction. Numerous round, pin-point, and flame-shaped hemorrhages gradually made their appearance in close proximity to the veins about 1 to 1.5 disc-diameters from the disc. The number increased,

and some coalesced to form large patches of hemorrhage. Later, large, nummular, disc-size, brick-red hemorrhages appeared one to two disc-diameters from the margin of the disc. As the volume of the hemorrhages increased they became dark red. The picture resembled central retinal thrombosis except that the hemorrhages lacked continuity with the disc. After thirty minutes of observation the left eye, too, showed arteriolar spasm and venous congestion but no hemorrhage or papilledema. The patient died three hours later. Autopsy showed massive subarachnoid hemorrhage over the right base of the brain, extending into the right optic sheath, and taking origin from the right anterior cerebral artery at the circle of Willis.

Livingston, P. C. Visual problems of aerial warfare. 1. "Night": studies in the dark-adapted eye. The Lancet, 1944, v. 247, July 8, p. 33.

The swing of retinal function between rod and cone depends upon the amount of available light. It is known that in full moonlight cone function is dominant, with the assistance of rods

in an advanced but not complete state of adaptation. In good weather, night operations during the summer months are largely within the range of cone vision, suggesting the importance of due consideration of cone activity.

Normally the dark-adapted eye reveals a central scotoma corresponding to the size of the macula when tested by luminous objects below cone threshold. Measurement within small variations is 4 degrees wide and 5 degrees high. Variation in pattern demonstrates that recognition of objects whose illumination is gradually increased is greater and more rapid in those individuals who have the smallest scotoma, or the smallest pure cone area centrally. Likewise those with larger cone areas do poorest at the above recognition. Earlier experiment revealed that form recognition drops rapidly outside of 5 degrees from fixation in the dark-adapted eye. Enlargement of the blind spot is normally found on rod perimetry as is an interesting area of rod hypersensitivity between 12 and 18 degrees above the fixation point.

By these methods vitamin-A-deficient subjects show first an enlargement of the blind spot with early break through to the periphery. The normal central scotoma enlarges beyond physiologic limits, with later a concentric peripheral field contraction.

Rod sensitivity under anoxic conditions is found to vary widely in different subjects, the cause of which is still open to speculation. It has been found however that rod function is much less resistant to anoxemia than cone function. Owen C. Dickson.

MacDonald, A. E. So-called primary retinal tuberculosis. *Trans. Amer. Ophth. Soc.*, 1943, v. 41, pp. 197-199.

MacDonald adds another case of so-called primary retinal tuberculosis to the two cases previously reported by O'Sullivan and Story and by Hancock. The salient clinical feature of these two cases was the brilliant white reflex seen ophthalmoscopically. MacDonald's case had a similar reflex. Pathologic examination of his case revealed many mononuclear leucocytes in the iris and ciliary body. Two areas of cascation were seen in the retina. No giant cells were detected. MacDonald suggests that absence of giant cells was probably due to the early phase of the disease. (3 photomicrographs, references.) Carl D. F. Jensen.

Marshall, J. C. A case of polycythemia vera—extraction of both lenses. *Brit. Jour. Ophth.*, 1944, v. 28, Oct., pp. 481-486.

Robertson, G. W., and Yudkin, J. Effect of age upon dark adaptation. *Jour. of Physiology*, 1944, v. 103, June, p. 1.

Disagreement as to the effect of age upon dark adaptation is considered due to differences in technique of measuring dark adaptation. In their measurement of dark adaptation (final rod-threshold) in 758 factory workers between the ages of 14 and 71 years, these investigators have found a progressive lowering of the power of dark adaptation with advancing years. The deterioration varies in different decades, the greatest being between fifty

and sixty. Progressive decrease in size of the pupil explains this deterioration quantitatively. Comparison of individual values with any normal standard is not considered satisfactory, since the normal range of dark adaptation is fairly wide. Francis M. Crage.

Sheard, C., Wagener, H. P., and Brunsting, L. A. Disturbances of visual adaptation and their clinical significance. *Proc. Staff Meetings Mayo Clinic*, 1944, v. 19, Nov. 1, p. 525.

The physiology and chemistry of dark adaptation and the criteria for its precise measurement are fully described.

Since vitamin A is a constituent part of the photosensitive pigment of the rods and, perhaps, also of the cones, night blindness can be produced in some instances through dietary avitaminosis A. Similarly night blindness will result in cases in which the vitamin A of the normal diet cannot be absorbed in the gastrointestinal tract, or in cases of malnutrition due to ulcerative colitis. On the other hand, feeding with large doses of vitamin-A concentration in frank conditions of vitamin-A deficiency will result in a recovery, which, however, may require weeks or months.

The tissues of the skin need carotene and vitamin A for their nourishment. Inadequate amounts of vitamin A in the blood and tissues may be found in certain skin diseases, such as pityriasis rubra pilaris and keratosis follicularis, and in these diseases the threshold of dark adaptation is very high. The liver is a great storehouse of vitamin A. Diseases of the liver, such as cirrhosis, are commonly associated with abnormal dark-adaptation curves.

The concentric contractions of the visual fields and the typical dark-

adaptation curves may be used clinically as points in differential diagnosis between primary pigmentary degeneration of the retina and inflammatory disorders. In some dyskeratotic diseases, although the threshold level of dark adaptation was found to be very high, the patients seemed to be well nourished and carotene was found in excess in the blood. We must assume that in these cases there was some disturbance of the mechanism for converting carotene into vitamin A, a process which takes place in the liver, although the commonly used liver-function tests failed to reveal any liver damage.

Stallard, H. B. Retinal detachment; 78 cases in the Middle East. *Brit. Med. Jour.*, 1944, Sept. 9, p. 329.

This article supplies statistics on 78 cases of retinal detachment, including 13 cases caused by cystic degeneration, 21 by choroido-retinal degeneration, 3 by myopia, 23 by civil trauma, and 18 by military trauma. All but two of the 78 cases were operated upon by combined surface and penetrating diathermy. The important features of the tears and special details in the cases operated upon are described. A table giving the postoperative results indicates 100 percent success in the cystic-degeneration and choroido-retinal-degeneration groups, both totalling 34 cases. Least favorable were the war trauma cases. Francis M. Crage.

11

OPTIC NERVE AND TOXIC AMBLYOPIAS

Ford, Rosa. Retrobulbar neuritis (five cases) due to paranasal sinusitis. *Brit. Jour. Ophth.*, 1944, v. 28, Oct., pp. 511-515.

The five cases showed marked visual

defects. The duration of symptoms varied from two months to 29 years. All showed remarkable improvement in the vision following continuous drainage of the sinuses. In every case the sinusitis was silent.

Because of the prompt and steadily progressing visual improvement, the author believes that in these cases the term "pressure paresis of the optic nerve" is more suitable than "retrobulbar neuritis." (References.)

VISUAL TRACTS AND CENTERS

Livingston, P. C. Visual problems of aerial warfare. 2. "Day": studies of photopic vision. *The Lancet*, 1944, v. 247, July 15, p. 67.

The organ of sight, when weak in some part, develops a compensatory mechanism, reflected in an adjustment of function within the cerebral cortex, which goes far to overcome the defect. It is not so much the presentation of an abnormal pattern resulting from an inherent defect which defeats the accuracy of analysis; it is an alteration in that pattern.

This accounts for the frequent tolerance of high astigmatic errors, and possibly the intolerance of small errors. Cases referred for refraction, especially under the stress of war, fall into two groups, (1) the tolerant, basically calm; and (2) the intolerant, those tuned to a higher cortical pitch. If a possible cause for visual irritation is discovered in the intolerant, it should be corrected. Indications for treatment are: (a) a sensation of relief emphasized by the patient with the correction; (b) great sensitivity to change of axis while rotating a small cylinder; (c) appreciation in an abnormally high

degree of small alterations in spherical power. Any of these suggest that effort in seeing has been transferred from the subconscious to conscious levels.

Factors influencing design of goggles for flying personnel include (1) adjustable interpupillary distance to allow quantity production; (2) use of safety glass to protect against shattering or flame; (3) design to give the greatest possible field of vision, accomplished partly by use of a double glass with two windows on each side, necessary because the safety glass cannot be ground on a high curve; (4) lightness to avoid the effects of gravity in flight.

Closed-cabin flying makes use of spectacles possible, with advantage in enlarged field and decrease in misting, but with the disadvantage of decreased protection.

Contact lenses have not been perfected to the place where they are of significant value except in isolated instances.

Glare has been controlled by use of "polaroid" or by Crookes B2 lenses.

Heterophorias can first be broken into two groups—those which are present from an early age, and usually stable, and those acquired, usually being unstable. The former commonly produce no symptoms while the latter do. The psychologic effect on the flier when elements of eyestrain develop are tremendous and difficult of evaluation. The consciousness of the need for effort in focusing results in discomfort, irritability, and eventually fatigue—a fatigue which may develop into a neurosis.

The author presents charts giving the results of orthoptic treatment in regard to exophoria, esophoria, and convergence insufficiency. Orthoptic study of 1000 cases of heterophoria re-

veals the greatest advantage from training in convergence weakness and uncomplicated exophorias. Those cases complicated by a strong psychologic factor do not respond readily to any training. Esophoria approaching strabismus, exophoria complicated by neglect, and hyperphoria exceeding 3 prism diopters offer serious barriers to treatment. In training of the heterophorias 242 of 700 have qualified as pilots, 214 have reached the solo flying stage, while 38 failed to pass the ground examinations. The remainder were reclassified for various reasons. In addition to the correction of the phoria, reinforcement of stereopsis is important because of the demands of present flying.

Central vision in the light-adapted eye appears little affected by anoxemia even up to the point of unconsciousness. Ophthalmoscopic examination reveals definite bluing of the disc under anoxemia. However, the effort required to maintain binocular concentration as tested by parallax cannot be sustained at high altitudes, while both accommodation and convergence decrease over a gradual curve with increase in anoxemia.

At extreme altitudes depression of the periphery of the visual field and localized regions of depression within the field occur. Further research may indicate whether this is due to nitrogen in the capillaries of retinal or of calcarine regions. The potential seriousness of the latter is apparent.

13

EYEBALL AND ORBIT

Rogalski, T. A contribution to the study of anophthalmia with description of a case. *Brit. Jour. Ophth.*, 1944, v. 28, Sept., pp. 429-440.

A case of left anophthalmia with a left-sided harelip is reported. The left palpebral fissure was narrower and shorter than the right, as a result of fusing of the eyelids near the lateral angle. The medial angle of the palpebral fissure was bisected by a ridge of skin that began in a shallow groove connecting the orbit with the harelip. This ridge of skin ran upward and laterally into the conjunctival cavity. At the lateral end of the ridge a black spot was visible through the conjunctival covering.

Dissection of the right orbit showed the contents to be entirely normal. The left orbit, however, showed the left ophthalmic artery to be one third narrower than the right, and the left optic nerve was completely absent. The left optic foramen was smaller than the right and the ophthalmic artery was the only structure passing through it. The left orbit was distinctly smaller than the right. The left nasolacrimal canal was closed by a thin membrane at its nasal end.

Some of the contents of the left orbit were normal in appearance. The left lacrimal gland was well developed and the lacrimal puncta and canaliculi were present in both eyelids, but there was a bifurcation of the lower canaliculus to form two parallel channels.

The fundus of the conjunctival cavity was composed of dense fibrous tissue into which the orbital muscles were inserted in normal relative positions. No vestige of retinal structure, of optic nerve, of lens, or of hyaloid artery could be found in the left orbit.

Analysis of the contents of the left orbit showed that the mesodermal structures, situated external to the eyeball, were well developed, but that the eyeball itself was represented only by its anterior part, including vestiges of

cornea and sclera and of muscles and vessels. Among the parts to which the surface ectoderm gives rise, there were vestiges of everything but the lens. The lacrimal apparatus showed only slight maldevelopment.

The author suggests that the apparently independent development of the retina proper and the pigment epithelium, which have a common origin in the optic outgrowth, may be due to a difference in their blood supply.

Definitions of anophthalmia (complete and consecutive) and microphthalmia are given. The case presented belongs to the consecutive type of anophthalmia, in which the optic vesicle has certainly been formed but has atrophied in the very early stages, leaving as its vestige more or less malformed pigment epithelium. (6 figures.)

EYELIDS AND LACRIMAL APPARATUS

Dimitry, T. J., and Mijares, I. The treatment of trichiasis with choline. *Amer. Jour. Ophth.*, 1944, v. 27, Dec., pp. 1425-1427.

Foster, John. Reconstruction of the lower lid by Hughes's method. *Brit. Jour. Ophth.*, 1944, v. 28, Oct., pp. 515-519.

Two cases of reconstruction of the lower lid following surgical removal because of basal-cell carcinoma unsuitable for irradiation are described. Because of the difficulty of anesthetizing the inner surface of the tarsal cartilage and conjunctiva, the author recommends the use of intravenous anesthesia. (8 photographs.)

Edna M. Reynolds.

Gordon, S., and Cragg, B. H. Congenital ectropion associated with bilat-

eral ptosis. *Brit. Jour. Ophth.*, 1944, v. 28, Oct., pp. 520-521.

Congenital ectropion of all four eyelids was associated with ptosis of the upper lids. The patient's father, two brothers, and one sister had similar defects, although not so marked. Lashes were normal in position and distribution, and there was no clinical or X-ray evidence of bony abnormality of the face. There was an alternating hyperphoria and alternating convergent strabismus of about 15 degrees. Vision was 6/12 in each eye and a high degree of hyperopic astigmatism was present. Lenses did not improve vision. The fundi were normal. A thin Thiersch was placed in each upper lid and Wolff grafts in the lower lids. Four months later, fascial slings to the frontalis muscle were placed to overcome the ptosis. (2 photographs.)

TUMORS

Cordes, F. C. Bilateral metastatic carcinoma of the choroid, with X-ray therapy to one eye. *Amer. Jour. Ophth.*, 1944, v. 27, Dec., pp. 1355-1370; also *Trans. Amer. Ophth. Soc.*, 1944, v. 42. (6 figures, bibliography.)

Jackson, Harvey. Orbital tumors. *Brit. Jour. Ophth.*, 1944, v. 28, Sept., pp. 472-478.

This was the subject for discussion at a meeting of the Royal Eye Hospital Clinical Society. Holmes Smith, the Chairman, pointed out that considerable interest had been caused by Dandy's book on orbital tumors in which he claimed that most orbital tumors had intracranial extensions and should be dealt with through the transfrontal approach by the neurosurgeon and not

merely tinkered with by ophthalmic surgeons in Krönlein operations.

Jackson remarks that the most frequent and commonly the earliest symptom is unilateral proptosis. Disturbances of vision are often realized simultaneously with protrusion of the eye. Pain fails to play a part in the average history of an orbital-tumor case. This surprising freedom from pain is probably due to the chronicity of the majority of the lesions. The development of a mass discernible to the patient is infrequent. Other, less frequent, clinical signs of orbital tumor are ptosis or edema of the lids, chemosis, cranial nerve palsies, audible bruits, and formation of a discharging sinus resulting from secondary infection. Ophthalmoscopic examination reveals papilledema in optic-nerve tumors and optic atrophy in other types. The duration of symptoms when fully established may be very great. A period of from 12 to 20 years is not exceptional. Radiologic verification is possible in a high percentage of cases.

It is the opinion of the author that the Krönlein operation has little to offer because of the limited field it provides, the unsightly scar that it leaves, and the diplopia which so often results. He prefers the transcranial operation, on which the orbit is explored through its roof by a trained neurosurgeon. The scar is hidden and a much wider field of exploration is secured. (References, 7 figures.)

Edna M. Reynolds.

Michaelson, I. S. Angioma of the retina. *Brit. Jour. Ophth.*, 1944, v. 28, Oct., pp. 522-526.

A case of angioma of the retina in which a tear as well as a tumor of the retina was present is reported. Surface diathermy was applied over the site of

the tumor and over the site of the tear. Visual acuity improved from 6/36 to 6/9 and the visual field was enlarged. The tumor appeared to be occluded. The feeding artery was normal in size and the draining vein could not be traced. (2 fields, 2 drawings.)

Edna M. Reynolds.

Town, A. E. Myxoma of the lower eyelid. *Amer. Jour. Ophth.*, 1945, v. 28, Jan., pp. 68-69. (One figure.)

Wolff, Eugene. A note on the rosettes, nature, and nomenclature of "glioma retinae." *Brit. Jour. Ophth.*, 1944, v. 28, Sept., pp. 448-450.

The columnar cells constituting rosettes are shown to be identical with the neuroepithelium of the third or fourth month of gestation. From the general form of the cells, and the presence of an external limiting membrane and diplosomes, there can be little doubt that the rosettes represent developing rods and cones. (5 figures, references.)

INJURIES

Adamiuk, V. E. Therapeutic transplantation of skin. *Viestnik Oft.*, 1943, v. 22, pt. 4, p. 12. (See Section 2, Therapeutics and operations.)

Callahan, Alston. Eye injuries at an aircraft plant. *Jour. Med. Assoc. Georgia*, 1944, v. 33, Oct., p. 312.

A series of 404 eye injuries observed at an aircraft plant between January, 1942, and October, 1943, is presented with an evaluation of some of the clinical and therapeutic problems encountered. In most cases the traumatic agents in these cases were either particles of concrete or of similar substances or of various types of metal, particu-

larly aluminum and light alloys used in the construction of airplanes. A technical procedure evolved for the removal of minute foreign bodies from the cornea is described. Attention is called to the chemical sensitiveness of the eye to aluminum particles; and two cases of successful extraction of intraocular foreign bodies are described. Theodore M. Shapira.

Cherkasky, E. B. The best time to enucleate crushed eyes. *Viestnik Oft.*, 1943, v. 22, pt. 4, p. 28.

In grave war injuries leading to destruction of the eyeball there is usually severe conjunctival chemosis and ocular immobility caused by retrobulbar hemorrhage or orbital damage. Frequently the picture is mistaken for panophthalmitis and so the eyeball is eviscerated. Cherkasky is opposed to evisceration because he fears that uveal particles may be overlooked and become the source of sympathetic ophthalmia. Enucleation can be performed more easily and the postoperative recovery is smoother if the operation is done after the traumatic reaction subsides. He therefore urges delay of the operation for 20 to 25 days, until the orbital hemorrhage is absorbed and ocular motility is restored. Experience in war injuries has shown that frequently a foreign body passes through the eyeball and lodges in the cranium. For this reason such cases should be X-rayed before the eyeball is removed, and the latter should be done only when the conjunctival sac becomes free from purulent secretion. Ray K. Daily.

Cogan, D. G. Lewisite burns of the eye. *Jour. Amer. Med. Assoc.*, 1943, v. 122, June 12, p. 435.

Two instances of ocular lesions in man resulting from exposure to lewisite

droplets and gas are reported. The chief manifestations were in the superficial cornea, and caused severe epiphora, photophobia, redness, and swelling. There was no permanent damage. The relative mildness of the ocular lesions is probably accounted for by the prompt epiphora which flushes out the irritant, as contrasted with the latent period of mustard gas.

Robert N. Shaffer.

Golitsyn, N. D. Action of land mines, directed at the infantry, on the eye. *Viestnik Oft.*, 1943, v. 22, pt. 4, p. 30.

These mines striking at close range are very destructive, damaging the face, the eyes, and other parts of the body, and are frequently fatal. In 80 percent of the cases they produced complicated burns of the face with damage to the bones of the face and orbit, and perforations of the eyeball. Their effects differ from the injuries produced by mines directed at the artillery, in that the latter, exploding further away, do not produce burns. In 40 percent of the cases there were also injuries to the upper or lower extremities.

The burns of the face usually involve the lids, the conjunctiva, and the cornea, with the formation of vesicles and subsequent swelling of the conjunctiva and cornea, as well as maceration and desquamation of the epithelium. Of these injuries 24 percent were slight, 68 percent severe, and the others fatal. In the fatal cases there were perforating injuries of the eyeball, orbit, and skull, and prolapse of brain tissue.

The clinical course of slight injuries is as follows: On the first day the swelling and edema are so extensive that inspection is impossible without lid elevators. After one to three days of treatment the injured begin to discern figures and outlines. Burns of the

cornea are very severe. Some cases show rupture of the cornea, traumatic cataract, and prolapse of vitreous. The explosions also produce contusions, hemorrhages in the conjunctiva, vitreous opacities, and hemophthalmos.

Treatment was by the open method, painting the skin with 3 percent potassium permanganate, and irrigating the eyes with a 1 to 4000 solution. In perforating wounds sulfanilamide powder was used. Except in perforating injuries bandages were avoided.

Ray K. Daily.

Krol, A. G. Surgical procedure in lid injuries. *Viestnik Oft.*, 1943, v. 22, pt. 4, p. 6.

According to Russian data injuries of the lids constitute 11 percent of all ocular injuries. Incorrect handling of these injuries leads to the formation of thick scars, colobomas, and synechias between the lids and conjunctiva. The patient is thus left with a cosmetic deformity and disturbed function. Failure to do a primary repair of the lids, and waiting for cicatrization, keep the wounded in the hospital unnecessarily for months, and the results of late repair are not always satisfactory. Failure to undertake primary repair is usually due to fear of infection. But in reality the danger of infection of the lids is minimal, because the abundant vascularization of the tissues and the thinness of the muscle tissue insure excellent nutrition. War surgery has demonstrated that the earlier the repair of the lids is performed the better the results. Analysis of 64 patients, 23 of whom were operated upon within one to 22 days of the injury in field hospitals, and 41 at base hospitals from one to three months after the injury, shows that injuries of the lids should receive primary repair in field hospitals,

and when hospitalization is late they should have immediate repair and remain in the hospital until the sutures are removed. The wound should be repaired even if the wounded reach the hospital after a delay of 1 to 3 weeks, and one should never wait for complete cicatrization of the wound. In operating, every millimeter of tissue should be carefully saved. In wounds through the entire thickness of the lids the conjunctiva and the skin should be sutured separately, and the lids should be totally immobilized for four days with a binocular bandage. Postoperative physiotherapy is of value in reducing the density of the cicatrices.

Ray K. Daily.

Kronenberg. Bernard. A case of intralenticular foreign body with early removal. *Amer. Jour. Ophth.*, 1944, v. 27, Dec., pp. 1427-1428.

Mann, Ida. A study of eighty-four cases of delayed mustard-gas keratitis fitted with contact lenses. *Brit. Jour. Ophth.*, 1944, v. 28, Sept., pp. 441-447.

The cases reported were diagnosed on the history and on the finding of mustard-gas scars with corneal degeneration (fat and cholesterine), varicose conjunctival and corneal vessels, and avascular scars on the interpalpebral conjunctiva. Roughly half of the cases had a long quiescent interval between exposure and the beginning of the ulceration stage. The only complaint during this time was alteration of refraction. The recurring ulcers heal but leave faceted scars which gradually diminish visual acuity.

Wearing contact glasses does not entirely prevent breakdown, but in many cases retention of vision and continuance of work has been made possible for as much as seven years. In all but

two cases, moreover, there was great improvement in vision with contact glasses. Thirty-nine of the patients wear their contact glasses eight hours or more a day. Twenty of these patients have had one or more relapses since wearing the glasses. Five patients have been unable to wear contact lenses, and eight patients wear their lenses less than five hours a day. (One graph, 2 tables, references.)

Edna M. Reynolds.

Michaelson, I. C. Incomplete avulsion of the eye. *Brit. Jour. Ophth.*, 1944, v. 28, Sept., pp. 458-460.

The case is reported because of the remarkable functional recovery. A soldier assaulted the patient, and attempted to gouge out his right eye with a spike-ring. There was a clean-cut, oval, incised wound through the upper and lower lids, including the conjunctiva. The globe was proptosed between the edematous tissues and could not be replaced. All four recti muscles were completely severed from their global attachments. The vitreous showed extensive hemorrhage, which together with the corneal haze prevented a view of the fundus. The visual acuity was perception of hand movements.

Under general anesthesia the recti muscles were sutured to their insertions, the conjunctival wound was closed, and the lids were brought back in position. After seven weeks the vision was 6/24 and the vitreous had greatly cleared. After 16 months, when the patient was seen again, he was complaining of some diplopia when looking forward and to the left. The right eye showed some divergence and some limitation in adduction. The right eye showed a pronounced optic atrophy. With central acuity of 6/9, the visual loss was not in keeping with the

marked pallor of the disc. The field showed some concentric contraction and a small paracentral scotoma.

The right external rectus muscle was lengthened surgically. At the time of discharge, all movements of the eyes were good except that there was adduction of the right eye in binocular use. (One field, 3 figures.)

Mitzkevich, L. D. Wounds at the inner angle of the lids and treatment of the resulting defects. *Viestnik Oft.*, 1943, v. 22, pt. 4, p. 10.

In repair of injuries of the lower lid at the inner canthus, Mitzkevich pulls up the torn loose end of the lid into a pocket formed high up under the skin of the inner canthus, and sutures it there with two mattress sutures. The buried end of the lid should be denuded of the outer skin layers. This procedure fixes the lid firmly in its place and avoids the ectropion and eversions so commonly seen in end-to-end repair of such wounds. (Illustrations.)

Muraviev, B. G. A modification of Keller's method in localization of intra-ocular foreign bodies. *Viestnik Oft.*, 1943, v. 22, pt. 4, p. 37.

The author's modification consists in dividing the exposure time unequally, to produce two X-ray shadows of unequal intensity. The patient looks down for one-third of the exposure time, and up for two-thirds. If the lighter shadow on the roentgenogram is found below the denser one, the foreign body is located in the anterior ocular segment while if their position is reversed it is in the posterior ocular segment. This method may be used when equipment required for more accurate localizing methods is unavailable, and is suitable

for foreign bodies not less than 1 mm. in size.

Ray K. Daily.

Pfeiffer, R. L. Localization of intra-ocular foreign bodies by means of the contact lens. *Arch. of Ophth.*, 1944, v. 32, Oct., pp. 261-266.

The removal of magnetic foreign bodies by the hand magnet is somewhat replacing the grosser technique employing the giant magnet. This more refined technique calls for more accurate localization. With consummate care it is possible for a roentgenologist to localize a foreign particle in the eye with greater accuracy than the surgeon can utilize at operation.

Bone-free roentgenography, employing dental film, is of value both in the diagnosis and localization of fragments in the anterior 8 to 12 mm. of the eye. For more general use, localization is carried out by means of the Comberg contact lens. This lens differs from optical contact lenses in that it contains four lead markers to indicate the limbus. With the contact lens in place, two exposures are made, a posteroanterior and a lateral. These two exposures make it relatively easy to determine the position of the foreign body in relation to the four lead markers. The method of plotting the position graphically is described. The author states that this method is accurate, simple, easy to perform, and adaptable, and that it requires a minimum of apparatus. (7 figures, references.)

John C. Long.

Pierce, G. W. Some useful plastic procedures in ophthalmology. *Trans. Amer. Acad. Ophth. and Otolaryng.*, 1944, 48th mtg., May-June, pp. 309-332.

After complete excision of an apparently small scar, an appalling defect often results. Only experience teaches

the best selection of materials for repair of the part. Nine illustrative cases are recorded.

A severe ectropion of the lower lid following a boiler explosion was successfully treated with a skin graft from the back of the ear. Ptosis following a conjunctival burn complicated by orbital infection was improved by insertion of two subcutaneous fascia-lata strips. These extended from slightly below the tarsal fold to a half inch above the brow.

Obliteration of the cul-de-sac following a lime burn was remedied by a thin Thiersch-graft inlay fitted on a bisected wax mold. Scar tissue was previously completely excised. A similar problem was solved by scar-tissue excision and the restoration of the lower cul-de-sac by mattress sutures from the conjunctiva downward through the lower lid.

Entropion was improved by a modified Machek-Blaskovics operation. Extensive melanoma of the lower lid was excised and the lid repaired with a pedicled flap from the temporal end of the upper lid.

After a bullet wound, the orbit was reconstructed with a Thiersch graft splinted with dental modeling-wax. An acrylic plug was placed in the orbital apex on which rested the prothesis. A preserved refrigerated cartilage-implant was placed subperiosteally in the floor of the orbit to raise the eyeball and relieve diplopia following a crushing fracture of the malar bone. (21 photographs, 34 diagrams.)

Popov, M. Z. Pathogenesis of the fundus changes in complicated cranio-cerebral injuries. *Viestnik Oft.*, 1943, v. 22, pt. 4, p. 19. (See Section 12, Visual tracts and centers.)

Protopopov, B. V. Signal forceps for removal of nonmagnetic intraocular foreign bodies. *Viestnik Oft.*, 1943, v. 22, pt. 4, p. 29.

The author has devised a forceps connected with an electric current and a small light bulb. A piece of metal between the blades of the forceps closes the circuit, the fact being indicated by the lighting of the bulb. The foreign body is localized by X ray. After a scleral incision over the foreign body the forceps is introduced into the wound and attempts are made to grasp the foreign body. In one case the lamp was lit immediately after the introduction of the forceps and the foreign body was easily extracted. In three cases it was removed after a long search. In two cases the attempt failed. In one of these the eyeball was enucleated and it was found that the foreign body had not been correctly localized by the X ray, and was enveloped by a dense exudate so that the forceps could not come into contact with it. In the second case the foreign body had been in the eyeball for a month, and had also probably become firmly encapsulated.

Sherman, A. R. Eye injuries in industry and determination of their disability. *Jour. Med. Soc. New Jersey*, 1944, v. 41, Sept., p. 332. (See Section 18, Hygiene, sociology, education, and history.)

Smelanski, R. I. Orbital foreign bodies. *Viestnik Oft.*, 1943, v. 22, pt. 4, p. 24.

In industrial injuries orbital foreign bodies are rare, because a sharp metallic particle usually penetrates and becomes arrested within the eyeball. Foreign bodies in the orbit result from double ocular perforations, and it is

generally agreed that they are best left alone. In war injuries the foreign bodies are large, and penetrating at a great velocity they are powerful enough to pierce the bony walls of the orbit, and sometimes of both orbits, at times missing the eyeball. The important symptoms due to intraorbital foreign bodies are exophthalmos, limitation of ocular motility, ptosis, edema of the upper lid, and edema or chemosis of the conjunctiva. Chemosis is a very important symptom, and the persistence of chemosis without inflammatory symptoms is very suggestive of the presence of an intraorbital foreign body. The ocular symptoms are those of contusion; paralysis of the sphincter, iridodialysis, vitreous hemorrhages, and ruptures of the choroid and retina. Localization of the foreign body is very difficult even with X ray, and so is its extraction, even with the giant magnet. A foreign body held firmly by the tissues of the orbit or its bony walls is not dislodged by the electromagnet. Surgery in such cases should not be undertaken hastily. While it is recognized that all intraocular foreign bodies should be removed immediately and there must be special indications to justify delaying the operation, in intraorbital foreign bodies the situation is reversed. Surgery should not be undertaken without definite indications. These are symptoms of beginning orbital infection, pressure symptoms caused by a large fragment, and beginning meningitis. Extractions should be undertaken after careful X-ray localization, and one should have available a giant magnet and a radio-localizer. The author's material consisted of 47 surgical cases. There were 41 metal fragments, 4 bullets, and in two cases the orbit contained pieces of bone; in one case it was the bone of a horse blown up by a mine, and in the

other a piece of the patient's own leg. The foreign bodies were localized as follows: 24 in the anterior portion of the orbit, 24 in the posterior portion, and 3 in the ethmoids. The eyeball was saved in 32 cases; in 29 with satisfactory vision and in 9 without vision. In 15 cases the eyeball was gravely injured. Of 45 foreign bodies, 30 were extracted through orbitotomies, one case by means of Kroenlein operation. Twenty-two foreign bodies were extracted with the giant magnet, and 6 with the aid of the radio-localizer.

Ray K. Daily.

Wiener, Meyer. The treatment of recent injuries to the eye and adnexa. *Trans. Amer. Acad. Ophth. and Otolaryng.*, 48th mtg., 1944, July-Aug., pp. 425-435.

All bleeding should be stopped before anything else is done. Digital compression, if properly carried out, will always temporarily control the major part of the bleeding. All bleeding vessels should be tied with silk ligatures cut short and left buried. Blood transfusions are indicated if the patient is in shock. General anesthesia may be necessary during the process of cleaning and preparing the wound. The cutting away of all lacerated and mashed tissues as was generally practiced during World War I has given way to more conservative methods. Wounds must not be disturbed too often for inspection. Adequate tetanus toxoid should always be promptly administered in deep wounds, especially if the opening is small. Gas-gangrene serum is indicated if the risks justify. Necrotic material and pus should be eliminated before administering sulfonamide therapy. Primary wound closure is usually dangerous, and with few exceptions wounds should be left open. Not more

than 10 gm. of sulfanilamide should be used locally on any patient within a 24-hour period.

In severe heat-burns of the body, intravenous plasma should be used immediately. Avoid débridement or cleansing, using only sterile boric-acid strips secured by pressure bandages. Skin grafts, if necessary, should be used promptly. Granulation tissue should be removed. In perforating cuts of the lids, avoid loss of marginal conjunctiva.

In deep lid cuts, deep sutures should be used before suturing the skin. Patients requiring plastic repair should receive only prophylactic measures by eye surgeons not trained in plastic surgery. These patients should only be operated upon where experienced plastic surgery is available.

Generally speaking, magnetic intraocular foreign bodies are best removed with a powerful magnet and through the sclera. The scleral incision should be made with a very sharp cataract knife, and should be considerably larger than the estimated diameter of the foreign body, and as near the localized point as possible.

All injuries to the ciliary body produce eyes potentially subject to sympathetic ophthalmia. Enucleation is advised at the first sign of eyeball shrinkage, such as pitting of the injured eye. Scleral ruptures practically always mean loss of the eye. Retinal detachment due to traumatism responds especially well to electric coagulation. Iris prolapses should be excised and not replaced. If possible, wait until all irritation has subsided before operating on perforating lens injuries. Dislocated lenses, unless removed, nearly always result in increased intraocular tension and loss of the eye.

Conjunctival and corneal burns due

to alkalies or acids should be treated by prompt flushing of the conjunctival sac with water, using considerable force. In superficial burns, use cool compresses; in deep burns from lye or other escharotics, warm applications should be used. In lye burns, as long as the conjunctiva and underlying sclera remain red, one need not fear more severe damage to the cornea than exists. Pickrell's solution of 3 percent sulfadiazine in 8 percent triethanolamine sprayed over the surface of heat burns involving the face or lids seems the best immediate treatment thus far used. First aid in gas burns consists of several minute irrigations with any bland nonirritating solution. Use atropine if the cornea is involved; also sulfathiazole ointment or jelly to help prevent secondary infection. Lewisite burns should be treated by irrigation with one or two percent sodium-bicarbonate solution. (References.)

SYSTEMIC DISEASES AND PARASITES

Campbell, A. M. G., and Cross, A. G. Ocular neurosis. *Brit. Jour. Ophth.*, 1944, v. 28, Aug., p. 394.

The incidence of ocular neurosis in wartime is estimated at 34 percent, as compared with 15 to 16 percent in peacetime. Fourteen cases are reported, and the fact is emphasized that the basis of a neurotic reaction is any factor which induces an abnormal awareness of the ocular mechanism. Most of the cases reported are of chronic anxiety neurosis. The author suggests better education of the public, to bring about an intelligent realization of the strength and potentialities of the normal eye, and eradication of the belief that close study and working in artificial light damage the eyes.

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Alvis, B. Y. Defective vision in industry. *Industrial Med.*, 1944, v. 13, July, pp. 537-539.

Industrial efficiency of groups of workers has a definite relation to the adequacy of their vision. Workers doing superior work for which their visual equipment theoretically or actually is not ideal compensate for their visual handicap by the factors of superior intelligence and training and experience. We must know the shortcomings of the workers so that they are not assigned tasks for which they do not possess the essential visual faculty. Safety and efficiency on the job are to be maintained, and danger to life and property from faulty vision must be avoided. The "art of seeing" is a composite of visual attributes including visual acuity, fusion and stereopsis, muscle balance and coördination, color appreciation, range of accommodation, and condition of visual fields. It is advisable to keep a record of the employee's ability in each of these components, first to direct placement, but also as a matter of record in case claims arise following accidental injury.

Crisp, W. H. Edward Jackson's place in the history of refraction. (First Jackson Memorial Lecture.) *Amer. Jour. Ophth.*, 1945, v. 28, Jan., pp. 1-12; also *Trans. Amer. Acad. Ophth. and Otolaryng.*, 1944, 49th mtg., p. 47. (Bibliography.)

Duke-Elder, Stewart. Caring for the eyes of Britain's Army. *The Military Surgeon*, 1944, v. 95, Aug., p. 105.

The ophthalmic services of the British Army have become revolutionized in the course of the war. At the periphery are the Mobile Ophthalmic Units, one to each corps, serving the needs of the front line. These units are carried on two trucks, one acting as an ophthalmic consulting room, the other as a spectacle shop. They carry an oph-

thalmic specialist and a sergeant optician, and full equipment for ophthalmic examination and treatment, including a giant magnet, diathermy, a generator, lenses, frames, and the necessary optical mechanical equipment.

The prompt treatment of minor eye casualties, including superficial foreign bodies, abrasions, conjunctivitis, and the remedy of damage or loss of spectacles, enables many men to return immediately to their fighting units. Thus, during a battle of El Alamein one Forward Ophthalmic Unit dealt with 590 eye or spectacle casualties in one week. Of these, 180 were serious injuries and were treated and evacuated to the base, while 410 were returned to their units the same day. To the early removal of intraocular foreign bodies, to prompt operation on corneal and scleral wounds or on prolapse of uveal tissue soon after the injury, is attributed a great deal of sight saving, although some credit must be given to advances in surgery.

R. Grunfeld.

Gutzeit, E. E. Medical-social aspects in the rehabilitation of the blind. *Outlook for the Blind*, 1944, v. 38, Sept., p. 196.

The number of blind persons who will benefit by the Barden-La Follette Act is not large. Only 15 to 25 percent are employable, that is from 34,000 to 56,000 persons. The remainder are disqualified by advanced age, household responsibilities, or handicaps other than blindness.

In order to guide the blind to vocational rehabilitation it is necessary to know what practical use can be made of the various degrees of vision from 0 to 20/200. For instance, what can be expected of a man whose sight has been restored by cataract surgery but who consequently has lost his accom-

modation? What work may a glaucoma patient do, or one with retinitis pigmentosa who has lost considerable peripheral field? What precautions must a diabetic patient observe in order not to lose more vision?

R. Grunfeld.

Hamilton, J. B. The incidence of eye disease in the Australian imperial forces, Middle East. *Brit. Jour. Ophth.*, 1944, v. 28, Aug., pp. 383-393.

This report covers 5,650 diseased conditions seen in 3,638 patients during 1941 and 1942. The report is compared with a previous publication by the author of 14,317 diseased conditions in a survey of 6,458 private patients seen in Tasmania between 1931 and 1939. The figures and percentages of civil and war eye disease are arranged in five tables for comparative study. A general survey shows that there is less eye disease in military than in civil life. There are fewer eye injuries, and on the medical side, the percentages of iritis, keratitis, choroiditis, retinitis, and retinal detachment are also lower in the army than in civil life.

The refractive errors in the army show a percentage of 64 as compared with 95 percent in civil life. Astigmatism was the commonest refractive error, being found in about 40 percent of the army cases. Muscular anomalies were recorded in 20 percent of the army cases as compared with 24 percent of the civilian cases. Hasty recruiting is the explanation advanced for the high percentages of refractive errors and muscular anomalies. There were as many amblyopias ex anopsia in army personnel as in civil life, which also shows hasty recruiting. Iritis and iridocyclitis were very rare in the army, possibly because of the early use of sulfanilamide by mouth. Not one case of

trachoma was found in the entire series. (5 tables.) Edna M. Reynolds.

Krakov, C. V. Physiologic optics in the Soviet Union for twenty-five years. *Viestnik Oft.*, 1942, v. 21, pt. 6. p. 42.

While studies in physiologic optics in Russia date from the last century, it was only after the Revolution that institutions devoted exclusively to the study of physiologic optics were established. The institutions established during the last 25 years in Moscow are: the Lazarev Institute of Biophysics with an extensive division for the study of vision; the laboratory of psychophysiologic sensations at the Institute of Psychology; the laboratory of physiologic optics at the Helmholtz Institute; the laboratory of physiologic optics at the Soviet Institute of Experimental Medicine; and the laboratory of technical illumination of the Safety Institute for Workers. In Leningrad is the laboratory of physiologic optics at the National Institute of Optics. Studies in the physiology of vision are being pursued in the department of physiology at the Military Academy of Medicine, in the technical illumination division of the Leningrad Institute for the Protection of Work, in the experimental laboratory of the Leningrad Ophthalmologic Institute, and in the First Leningrad Medical Institute. The Ukraine Ophthalmologic Institute pursues similar studies. Over a thousand publications have been issued in this field, and two volumes on problems of physiologic optics. Ray K. Daily.

Lake, M. M. Some observations on the problem of rural rehabilitation. *Outlook for the Blind*, 1944, v. 38, Oct., p. 221.

Among the branches of agriculture in which the blind may become suc-

cessful, are poultry raising, dairy farming, gardening, and marketing of products. But in each case the blind man needs assistance and supervision by his wife or some other member of the family. R. Grunfeld.

Livingston, P. C. Visual problems of aerial warfare. 1. "Night": studies in the dark-adapted eye. *The Lancet*, 1944, v. 247, July 8, p. 33. (See Section 10, Retina and vitreous.)

Livingston, P. C. Visual problems of aerial warfare. 2. "Day": studies of photopic vision. *The Lancet*, 1944, v. 247, July 15, p. 67. (See Section 12, Tracts and centers.)

Sanders, T. E. A method for the projection of eye specimens. *Amer. Jour. Ophth.*, 1944, v. 27, Dec., pp. 1424-1425.

Sherman, A. R. Eye injuries in industry and determination of their disability. *Jour. Med. Soc. New Jersey*, 1944, v. 41, Sept., p. 332.

Eye injuries in industry differ from other injuries only in that one must keep more detailed records on which he can base necessary reports. The author discusses various types of injury, common and uncommon. He also relates how the Medical Society of New Jersey standardized methods by which the percentage loss of vision was to be determined. This method was accepted by ophthalmologists and by the compensation courts of New Jersey. Other methods are also given. A method of determining visual-field loss is added. Theodore M. Shapira.

Shortley, M. J. Vocational rehabilitation for the visually handicapped. *Outlook for the Blind*, 1944, v. 38, Sept., p. 186.

The author, as Director of the Office of Vocational Rehabilitation of the Federal Security Agency in Washington, outlines the federal and state program of vocational rehabilitation. Until 1920 only private organizations were interested in the rehabilitation of the handicapped. The first vocational rehabilitation law was enacted in 1920. In the next 20 years 210,000 handicapped were rehabilitated throughout the United States. Federal funds were limited and the state legislatures were indifferent. Under the Barden-La Follette Act, which became law in July, 1943, federal funds are now available for medical and vocational diagnoses, vocational counseling, physical restoration, and vocational training with maintenance during training. All handicapped persons are eligible irrespective of financial status. Only static conditions may be treated and the medical services must be of such nature that they may reduce or eliminate substantially the employment handicap.

There are in this country about 230,000 blind persons, to whom must be added the partially sighted. The latter may be grouped as follows: (a) 25 percent general loss of vision, (b) loss of one eye, (c) 20/60 corrected vision in the better eye, (d) better than 20/60 vision if progressive. R. Grunfeld.

Sitchevska, Olga. Heredity and eye diseases. *Med. Women's Jour.*, 1944, v. 51, Oct., p. 17.

About 14 percent of blindness among children of school age and 10 percent of adult blindness are due to heredity. However, due to the complexity of hereditary mechanisms it is difficult to give definite advice to patients affected with serious eye diseases which have a hereditary tendency.

The dominant character of inheri-

tance in which half of the offspring will be diseased is manifest in congenital night blindness, blue sclerotics with bone fragility, ptosis, many types of cataract, ectopia lentis, coloboma of the iris, aniridia, familial types of corneal opacities, and certain types of myopia. In these, when two normal individuals marry, their progeny will never inherit the disease.

The recessive character is shown by retinitis pigmentosa, albinism, anophthalmos, buphthalmos, hydrophthalmos, and infantile glaucoma. Consanguinity is considered an important factor in the production of retinitis pigmentosa and albinism.

The most common type of transmission of the sex-linked character is that in which the descent is through the X chromosome, therefore dominant in the

male and recessive in the female. This type of transmission is present in Leber's optic atrophy, congenital color blindness, congenital nystagmus, and hemophilia. Sons of affected fathers are normal and do not transmit the disease, while the daughters appearing normal but possessing the recessive tendency transmit the condition to the males.

Microphthalmos may be either a recessive or a dominant characteristic in a hereditary strain. Some feel that microphthalmics should not reproduce and that no more children should be allowed parents of a microphthalmic child.

Keratoconus likewise may show definite hereditary tendencies, as may Groenouw's nodular keratitis.

Owen C. Dickson.

NEWS ITEMS

Edited by DR. DONALD J. LYLE
904 Carew Tower, Cincinnati 2

News items should reach the editor by the twelfth of the month

DEATHS

Dr. Scott C. Applewhite, San Antonio, Texas, died November 17, 1944, aged 68 years.

Dr. Aaron Brav, Philadelphia, Pennsylvania, died December 2, 1944, aged 69 years.

Dr. Joseph H. Crampton, Seattle, Washington, died November 9, 1944, aged 60 years.

Dr. John S. Gordon, Milwaukee, Wisconsin, died December 6, 1944, aged 56 years.

Dr. John E. Hiess, Perry, Oklahoma, died December 14, 1944, aged 60 years.

Dr. Jacob O. Hoffman, Harrisonburg, Virginia, died September 4, 1944, aged 84 years.

Dr. Frederick P. Parker, Saint Louis, Missouri, died November 18, 1944, aged 75 years.

MISCELLANEOUS

The complete program for the Ophthalmological Seminar which will be held April 19, 20, 21, 1945, in Atlanta, in honor of the memory of Dr. Abner Wellborn Calhoun, is as follows:

THURSDAY, APRIL 19, 1945

4:00 p.m.—Emory University Hospital Auditorium. Dr. W. I. Lillie, Philadelphia, "Clinical significance of diplopia."

5:00 p.m.—Reception—A. W. Calhoun Medical Library.

7:00 p.m.—Academy of Medicine. Buffet supper—Guest of Women's Auxiliary.

8:00 p.m.—Academy of Medicine. Dr. Frank B. Walsh, Baltimore, "Clinical diagnostic features of migraine."

9:00 p.m.—Dr. Walter I. Lillie, "Neuro-ophthalmology with special reference to retrobulbar neuritis."

FRIDAY, APRIL 20, 1945

10:00 a.m.—Grady Hospital Senior Lecture Room. Dr. Frank B. Walsh, "The ocular signs of subdural hematoma in infants and adults."

11:00 a.m.—Dr. William Benedict, Rochester, Minnesota, "Exophthalmos."

1:00 p.m.—Luncheon—Guest of Grady Hospital.

3:00 p.m.—Academy of Medicine. Dr. Parker Heath, Detroit, "Random notes on ocular surgery."

4:30 p.m.—Dr. William Benedict, "Discussion of superficial keratitis."

6:30 p.m.—Biltmore Hotel. Dinner—Guest of Emory University.

8:00 p.m.—Academy of Medicine. Dr. Parker Heath, "Some recent advances in ocular therapeutics."

9:00 p.m.—Dr. John Dunnington, New York City, "Surgical treatment of vertical deviations."

SATURDAY, APRIL 21, 1945

10:00 a.m.—Academy of Medicine. Dr. Harry Gradle, Chicago, "Observations on the surgery of retinal detachments."

11:00 a.m.—Dr. John Dunnington, "Plastic surgery of the lids."

1:00 p.m.—Biltmore Hotel. Luncheon—Guest of Eye Department.

2:30 p.m.—Academy of Medicine. Col. Derrick Vail, Cincinnati, "Ophthalmology in war."

3:30 p.m.—Dr. Harry Gradle, "Ocular complications of polyarthritides."

4:30 p.m.—Dr. John Dunnington, "Use of penicillin in ophthalmology."

6:30 p.m.—Biltmore Hotel. Dinner—Guest of Emory University.

8:00 p.m.—Academy of Medicine. Dr. Harry Gradle, "Surgical treatment of glaucoma."

9:00 p.m.—Col. Derrick Vail, "Ophthalmology in war."

The Saint Louis Ophthalmic Society and the Department of Ophthalmology of Washington University offers an eight-months' course for orthoptic technicians. The theoretical instruction will be given at the Oscar Johnson Institute and the practical work at the Saint Louis Ophthalmic Laboratory. The course is limited to three students; tuition \$300. For information write to the Saint Louis Ophthalmic Laboratory, Missouri Theatre Building, 634 North Grand Boulevard, Saint Louis 3, or to Dr. Lawrence T. Post, 640 South Kingshighway, Saint Louis 10.

The eleventh annual postgraduate course of the Virginia Society of Ophthalmology and Otolaryngology was held at the University of Virginia Department of Medicine, Charlottesville, December 5th to 8th. Participating in the program were: Drs. Paul H. Holinger, Russell L. Cecil, Frederick M. Law, John R. Page, Joseph D. Kelly, McLemore Birdsong, Marion Lawrence White, Jr., James W. White, Wendell L. Hughes, William E. Fry, and Paul A. Chandler.

According to a recent announcement the University of Illinois College of Medicine received an anonymous gift of \$20,000 for visual aid studies.

A course in slitlamp microscopy of the living eye combined with a course in glaucoma surgery was given by the Committee on Graduate Education of the Allegheny County Medical Society on February 12th to 14th. The course was conducted by the department of ophthalmology of Montefiore Hospital under the direction of Dr. Harvey E. Thorpe and his associates.

SOCIETIES

The Brooklyn Ophthalmological Society held its regular meeting on February 15th at the Towers Hotel, Brooklyn. A paper on "Wernicke's disease—encephalitis hemorrhagica superior" was presented by Dr. Daniel Kravitz and a discussion by Dr. Robert H. Stockfisch followed. The scientific program was concluded with a lecture by Dr. Raymond L. Pfeiffer on "Exophthalmos."

The Kansas City Society of Ophthalmology and Oto-Laryngology will present an oil painting of Dr. Hal L. Foster to the American Academy of Ophthalmology and Otolaryngology at the fiftieth anniversary of the Academy, provided the 1945 session is held. Dr. Foster founded the national organization at a meeting in Kansas City in April, 1896.

At the January dinner meeting of the Cleveland Ophthalmological Club, Dr. Harold Francis Falls of the Department of Ophthalmology, University of Michigan, spoke on "Ophthalmic syndromes." The lecture was illustrated with

lantern slides showing unusual cases which the speaker had observed.

The following officers have been elected by the Sociedad de Estudios Clínicos de la Habana for the biennium 1945-46: president, Dr. Julio F. Schulte Vicedo; vice-president, Dr. José Lastra Camps; secretary, Dr. Frank Canosa Lorenzo; vice-secretary, Dr. Luis Rodríguez Baz; treasurer, Dr. Luis Ortega Verdes; vice-treasurer, Dr. Alvaro Silva López del Rincón.

PERSONALS

Dr. Harry S. Gradle, President of the Pan-American Congress of Ophthalmology, who is now in South America on a speaking tour, has found all of the leading ophthalmologists in Latin America enthusiastic about the next meeting of the Congress, which is scheduled for November 25-30, 1945, in Montevideo, Uruguay. He has met with many of the South American ophthalmologists of the Congress and with the arrangements committee in Montevideo, and reports that the program is set up and all preliminary arrangements are completed.

Dr. Earling W. Hansen, Professor of Ophthalmology at the University of Minnesota School of Medicine, gave an instructive talk on "The mechanism of uveitis" at the November dinner meeting of the Cleveland Ophthalmological Club.

JUST BEFORE GOING TO PRESS WORD WAS RECEIVED THAT COL. DERRICK VAIL HAD BEEN APPOINTED CHIEF CONSULTANT IN OPHTHALMOLOGY, SURGERY DIVISION, IN THE SURGEON GENERAL'S OFFICE. THIS APPOINTMENT WILL PERMIT COLONEL VAIL TO RESUME A PART OF HIS EDITORIAL DUTIES ON THIS JOURNAL. THE STAFF WELCOMES HIM MOST HEARTILY AND CONGRATULATES HIM ON HIS NEW APPOINTMENT AND ON WORK WELL DONE OVERSEAS FOR THE LAST TWO AND A HALF YEARS. HIS ADDRESS IS COL. DERRICK VAIL (MC) 0491780, OFFICE OF THE SURGEON GENERAL, 1818 N STREET N.W., WASHINGTON, D.C.

*Pontocaine
Hydrochloride*

in

OPHTHALMOLOGY

and in

RHINOLARYNGOLOGY

*Surface Anesthetic
with Prolonged Effect*

Dependable anesthesia
of the mucous membranes

is readily obtained by the topical application of Pontocaine hydrochloride. This widely used agent acts quickly, penetrates deeply, and gives prolonged anesthesia. A variety of operative and nonoperative procedures on the eye, nose and throat may be successfully carried out with small quantities of relatively weak solutions.

HOW SUPPLIED: For surface anesthesia in ophthalmology: 0.5 per cent solution in bottles of $\frac{1}{2}$ oz. and 2 oz.

For surface anesthesia in rhinolaryngology: 2 per cent solution in bottles of 1 oz. and 4 oz.

*Not
a Narcotic*

RECURRENT EROSION OF THE CORNEA*

PAUL A. CHANDLER, M.D.

Boston

Recurrent erosion of the cornea is one of the most remarkable disorders of the eye. A patient suffers an injury to the cornea, perhaps a real abrasion with extensive loss of epithelium, perhaps a very slight trauma to the epithelium. The cornea heals in a period of hours or days, depending on the extent of the injury, and the patient becomes symptom-free, with the eye showing no resulting opacity or other sign of injury. At some later date (days, weeks, months, or even years afterward) there is a sudden development of symptoms of greater or less severity, without any obvious cause. The symptoms subside, only to recur again and again, sometimes over a period of years at various intervals. Almost invariably each attack occurs at some time between 2 and 4 a.m. or when the eyes are first opened in the morning. At the time of a recurrence the patient suffers pain, photophobia, lacrimation, and blepharospasm. The objective signs vary from a faint clouding of the epithelium, best visible with the reflected light of the ophthalmoscope, in the mildest cases, to a large corneal bulla or erosion in the most severe. Between these two extremes one may find various grades of disturbance.

A certain type of injury to the cornea seems to predispose to recurrent erosion—notably sudden sharp abrading injuries, such as a scratch from a fingernail, from

a branch of a tree or plant, or from the edge of a piece of paper. Seldom does recurrent erosion follow removal of a foreign body of the cornea, or wounds extending into the stroma. Moreover, it seldom occurs if there is infection of the original abrasion with resulting formation of a scar. On the other hand, the whole symptom-complex may occur in eyes that have suffered no known preceding trauma.

The disorder was first described in ophthalmic literature by Hansen in 1872,¹ under the name "Intermittent neuralgic vesicular keratitis." Von Arlt, in 1874,² was the first to use the term "recurrent erosion of the cornea," the name by which the condition has since generally been known. Von Szily, in 1900,³ in a paper entitled "Ueber Disjunction des Hornhautepithels" gave the most comprehensive discussion of the disorder, and pointed out the principal features of the disease.

From my own experience and from a review of the literature listed below, it is possible to distinguish two main forms of the disorder, for which I suggest the terms macro- and microform. Although the underlying pathology is probably identical in both forms, the clinical features, as a rule, are different enough to warrant separate discussion.

TYPES

The Macroform. As a rule, in this form there is a history of an extensive traumatic abrasion of the cornea. Recur-

*Read at the eightieth annual meeting of the American Ophthalmological Society, at Hot Springs, Virginia, May 29-31, 1944.

rences usually take place at long intervals, weeks, months, or years, with signs and symptoms similar to those of the original attack. This is the easily recognizable form, not very common, but familiar to most ophthalmologists, and many times reported in the literature. The involved area in a given recurrence is usually similar in location and extent to that of the original injury, but occasionally it does not correspond exactly in either location or extent.

The Microform. In this form there is usually, but not always, a history of corneal injury. As a rule the injury is a very slight one, for which the patient may not seek medical advice. The first attack usually occurs soon after the injury, often in a few days, in a few weeks at most. There is pain, lacrimation, and a sense of difficulty in opening the eyes. In from five minutes to an hour or two all symptoms subside. The attacks are much milder and of much shorter duration than those of the macroform, but occur far more frequently, sometimes every night or morning. When the patient presents himself with such a history, the eye is usually white and quiet, and the patient is symptom-free. The cornea appears clear and lustrous. If the last attack has occurred some days previously, it may be impossible to demonstrate any lesion of the cornea by any method of examination, including the use of the slitlamp. If the attack has occurred the night before, in the mildest cases, or even some days before, in the more severe, it is always possible to demonstrate a corneal lesion. This is small, usually 1 to 2 mm. in diameter, and may be anywhere in the cornea, though as a rule not within 2 mm. from the limbus. The disturbance may very easily be overlooked by ordinary methods of examination. Several of the earlier writers,^{4,5,6,7,8,9} unable to discover any corneal lesion in

this type of case, referred to the condition as "keratalgia." Many of my own patients had previously consulted several oculists, who had called the condition "neuralgia."

By far the best method of detecting the lesion is careful exploration of the cornea in a dark room with an ophthalmoscope, using a +4.00 lens. This was first demonstrated by von Szily.³ By this means one can discover the smallest corneal lesion, sometimes only a faint shadow in the epithelium. As von Szily also pointed out, in some cases a faint shadow in the epithelium can be brought out, or accentuated, by holding the eye open for a moment to permit some drying to occur, and then again moistening the cornea. Having thus located the lesion it can usually be seen with the slitlamp. With this instrument one finds one or two to half a dozen small grayish-white spots in the epithelium, some of which may stain with fluorescein. By using the highest power in the Zeiss slitlamp it can be seen that some of these dots are superficial vacuoles. Vogt¹⁰ reported seeing fine white dots in the epithelium, with the slitlamp, in the interval between attacks, and noted that in reflected light some of the dots appeared to be fine droplets. In some cases there is a slight unevenness of the surface, and definite localized epithelial edema. In others, where only the faintest shadow is visible with the ophthalmoscope, I have been unable to find the slightest disturbance with the slitlamp. Some disturbance of the corneal epithelium may be constantly present, even during the symptom-free period, or it may disappear entirely between attacks, only to recur again at a later time.

A few cases have been reported^{11,12,13,14} of bilateral involvement without any known preceding trauma. The lesions were bilaterally symmetrical in the two eyes, and usually located just below the

center of the cornea. Most of these cases have been of the severe macroform. I have observed one case of this sort, which was less severe than the usual macroform, but slightly more severe than the usual microform.

Franceschetti¹⁵ reported on six generations of a family 50 percent of whom were affected with recurrent erosion of the macroform. The tendency was transmitted as a dominant. Usually the trouble began with trauma, but not always. The first attack usually came at 4 to 6 years of age. The attacks became less frequent as the patients grew older, and did not occur after the age of 50.

FREQUENCY

The macroform is relatively rare. Most reports have been of from one to half a dozen cases, though Franke¹⁶ reported 60. I find in my files a record of nine cases of the macroform. On the other hand, the microform is not uncommon, although often unrecognized. I have observed 28 cases of this form, the majority during the past few years.

PATHOLOGY

Haab¹⁷ in 1890 was the first to point out that at the time of the recurrence the corneal epithelium was loosely attached and could be easily removed, sometimes from the entire cornea, save for a narrow rim around the periphery. Von Szily³ confirmed this finding, and discovered that even between attacks, when the cornea was entirely healed and the patient symptom-free, a large portion of the epithelium was easily removable, for at least as long as five weeks. Franke¹⁶ found the epithelium easily removable over a wide area in the mildest cases, as well as in the more severe. Peters¹⁸ pointed out that this looseness of the epithelium must be considered as a mild form of edema, consisting of a thin layer

of fluid under the epithelium, which at the time of an attack increased, sometimes even to the formation of vesicles or bullae. Pathologic examination of the epithelium in such cases by von Szily³ and Franke¹⁶ showed edema of the cells, sometimes fluid spaces between them, often rupture of cells and extrusion of their contents. The same condition to a somewhat less degree was found by von Szily even when the epithelium was removed in the symptom-free period. Franke likewise found the same pathologic picture in epithelium removed in the mildest cases. Peters¹⁸ first observed that in cases of corneal edema from other causes, such as herpes simplex, disciform keratitis and ulcer serpens, the epithelium was easily removable over a wide area, and this fact was also noted by Franke. This observation can be easily confirmed in any case of corneal edema. It seems clear, therefore, that some degree of epithelial edema is present in all stages of recurrent erosion, and is the principal feature of the disorder.

What is the cause of this edema? One of the most commonly accepted theories is that it is neuropathic in origin. Hansen,¹ the first writer on recurrent erosion, in terming the condition "intermittent neuralgic vesicular keratitis," evidently considered it to be a peripheral neuropathic process resulting from injury to the nerve endings of the cornea. Peters,¹⁸ in a thoroughgoing discussion of the subject, spoke strongly for the neuropathic nature of the disease. He assumed that the persistent epithelial edema was due to nerve disorder. He explained the recurrent attacks on the basis of further injury to the corneal nerves, resulting in more edema of the epithelium, so that sudden opening of the lids could further loosen or tear it off. Verhoeff¹⁹ in 1909, accepting the neuropathic theory, suggested that the original superficial trauma

to the cornea produced a condition of hyperexcitability in the Gasserian ganglion, and that the recurring corneal edema resulted from antidromic impulses passing backward from the ganglion along the sensory nerves. He felt that this explanation was not excluded in the nontraumatic cases, since it was conceivable that causes other than trauma could produce hyperexcitability of the ganglion. Salus¹² drew an analogy between the corneal edema of recurrent erosion and skin changes—blister formation, necrosis of the epithelium, and balloon degeneration, which can be produced experimentally by stimulation of vasomotor nerves. He cited Krubich, who in some cases was able to produce certain skin changes by local stimulation with such irritants as heat, cold, electricity. He thought these changes were due to indirect central stimulation of the vasomotor fibers in the cord by the sensory stimuli; that in the case of the eye, sensory stimulation, such as rubbing the eye in the nontraumatic cases, nerve injury in the traumatic cases, called forth this peculiar corneal response in the presence of an unstable vasomotor system. Other authors who accepted the neuropathic nature of the condition include Bronner,⁶ Procksch,¹³ Johelson,⁷ von Schroeder,²⁰ Wicherikiewicz,²¹ Bartels,²² Hirsch,¹¹ Gifford,²³ and Franceschetti.¹⁵ While the neuropathic theory is an attractive one, there is no real clinical nor experimental evidence in support of it. There can be no true analogy between vesiculation of the skin due to vasomotor influences, and corneal vesiculation, since in the former the changes are probably secondary to changes in capillary permeability, whereas in the latter case there are no blood vessels to be involved.

The recent experimental studies of Cogan and Kinsey²⁴ suggest an altered fluid exchange in the mechanism of edema

formation in the cornea, and may have some bearing on recurrent erosion of the cornea. Cogan²⁵ has shown that corneal edema and bullous keratitis may be produced by lowering the osmotic pressure of the fluid on the outside of the cornea. In the presence of a damaged endothelium and a hypertonic aqueous the epithelial edema occurred first and most extensively in the region overlying the damaged endothelium. According to this concept any defect in the endothelium would allow diffusion of electrolytes from the hypertonic aqueous into the stroma, thus increasing the osmotic tension of the corneal fluid in comparison with that of the tears, and causing edema.

In cases of persistent corneal edema after cataract extraction the evidence is very strong that a defective endothelium is the cause of the edema. In nearly all such cases careful examination will reveal either a primary endothelial dystrophy or an iris pillar, a piece of lens capsule, or a portion of the hyaloid membrane in contact with the back of the cornea in the region where the edema is first manifest.

For many years, I have had under observation a patient who is now about 82 years of age. Some years ago she developed glaucoma, for which an operation was performed. Later a cataract developed and an intracapsular extraction was done without complication. Her vision was good until she suffered a severe fall three or four years later, when her arm was fractured. While she was in the hospital being treated for the fracture the vision in the aphakic eye became very blurred. Examination showed considerable epithelial edema in the upper half of the cornea. Later a slitlamp examination was made, and it was found that vitreous was in contact with the back of the cornea in the upper part of the iris coloboma. Presumably the severe fall (which was

face forward) had ruptured the hyaloid and allowed vitreous to come in contact with the cornea. The corneal edema gradually became more marked, and bullae formed from time to time.

Recurrent vesicular or bullous keratitis has been reported after cataract or other intraocular operation,^{23,26,27,28} in chronic uveitis,^{23,24,29} in hereditary corneal dystrophy (Groenow),³⁰ and it is commonly observed in glaucoma. A defective endothelium in all these cases seems highly probable. In Fuchs's "epithelial dystrophy" in the earlier stages there is a "beaten silver appearance" of the back of the cornea, with no edema of the stroma or epithelium that is visible grossly. Later epithelial edema develops without obvious edema of the stroma, and it is only in the more advanced stage that frank edema of the stroma develops. Hence, even in cases where there is no apparent edema of the corneal stroma, a defective endothelium cannot be absolutely ruled out. After a corneal injury caused by an object striking it with some force, it is often possible to observe a cloudy zone on the posterior corneal surface directly behind the epithelial lesion. This clouding completely disappears in a few hours, but one cannot be sure when the endothelium has entirely returned to normal. Traumatic recurrent erosion commonly follows a type of injury where there is a sudden sharp forceful contusion which might conceivably damage a particularly susceptible endothelium. One of my patients suffered a slight injury to the cornea of her left eye when a twig struck it, and developed recurrent erosion of the microform. Two years later the other eye was struck by the corner of a piece of paper, and she developed recurrent erosion in this eye also. It would appear that her corneas were particularly susceptible to this type of trouble. A defective endothelium,

either as the result of direct trauma or other cause, as has been suggested by Cogan,²⁵ must therefore be considered in the persistent epithelial edema of recurrent erosion. Whether or not this concept is correct must await further clinical and experimental evidence.

Why do the attacks come only during the night or on first opening the eyes in the morning? There can be no doubt that the suction between lid and cornea can result in further loosening or tearing-off loose epithelium when the lids are suddenly opened. Patients often volunteer the observation that when they are suddenly wakened out of a sound sleep and open the eyes quickly, an attack is very likely to be brought on, whereas if the eyes are opened slowly and carefully there may be no trouble. Von Szily³ maintained that in the case of attacks coming in the middle of the night the patient always first awakened and opened the eyes, and then the attack commenced. That this is sometimes the case cannot be denied, but it is equally certain that some patients are wakened out of a sound sleep by pain in the eye before any attempt is made to open the eyes. De Schweinitz³¹ reported a case in which on several consecutive nights the patient was wakened out of a sound sleep by severe pain in the eye, and examination on each occasion revealed the presence of a large corneal bulla. As pointed out by Cogan²⁵ corneal edema from any cause is worse after sleep, presumably owing to the lessened osmotic tension of the tears overlying the cornea, when there is no surface evaporation. Patients with corneal edema frequently volunteer that their vision is worse after weeping, and this is again probably due to lowered osmotic tension of the tears in contact with the cornea. One of my patients, suffering from recurrent erosion of the microform, following a minor injury, stated that an

attack was invariably precipitated by weeping. Another patient had two attacks during the day, each time immediately after bathing in a fresh-water pool. Curdy³² reported a case of recurrent erosion of the cornea which was relieved by opening a stricture of the lacrimal duct. Any corneal edema can be made worse by bathing the eye with a hypotonic solution. Indeed, epithelial edema can be readily induced in any normal eye by a bath of hypotonic solution.³³

In recurrent erosion the attacks come only in the middle of the night, or on awakening in the morning, presumably due, at least in part, to an increase in the corneal edema caused by lowered osmotic tension of the tears. The prevention or amelioration of attacks by putting a bland ointment in the eye at bedtime has been reported in the literature,^{8,9,34,35} and I have found it extremely efficacious. Here the oily film on the surface of the cornea presumably prevents the imbibition of tears.

To explain the periodicity of the attacks, one could assume a temporary change in the osmotic balance between the corneal fluid and the tears. There is no doubt, however, that the manner in which the eyes are opened after sleep may determine whether or not an attack occurs. More difficult to explain is the efficacy of the generally accepted treatment of the macroform, consisting in removal of all loose epithelium, scraping of the cornea, and cauterization of the denuded area with a chemical agent, the fact that recurrent erosion practically never occurs in cases where there has been infection and scar formation, and that, during a recurrence, if there is infection and scar formation, no further attacks occur. In these cases there is more or less destruction of Bowman's membrane, and it has been assumed that the new epithelium then adheres so tightly to

the underlying stroma that fluid cannot collect beneath it.

TREATMENT

There is no doubt that in some cases the attacks sooner or later cease to occur, without treatment. Since it is impossible to predict which patients will continue to have recurrences, it is best to employ radical treatment only in cases in which there have been many severe attacks at relatively short intervals.

The favorable effect of putting a mild ointment in the eye at night has already been cited.

Three cases have been reportedly cured by the use of 5-percent Scharlach R ointment and a pressure bandage, followed by the use of 3-percent boric ointment in the eye every night for three months.³⁵

A bland ointment plus massage of the eye has also been recommended,^{36,37} as well as the use of a pressure bandage for several days after an attack.³⁸

X-ray therapy has also been advocated.^{27,39} Beneficial effect has been reported with quinine,^{11,23} and by the use of vermifuges.¹⁴

From a study of the literature one cannot fail to be impressed by the efficacy of treatment consisting in removal of all loose epithelium, scraping the cornea, and cauterization with a chemical agent.^{3,9,12,16,23,29,36,40,41,42,43} Franke¹⁶ reported 60 cases treated in this manner, using chlorine water as the cauterizing agent, with cures in all but two. In addition to chlorine water,^{9,12,16} trichloroacetic acid²³ and iodine²⁹ have been used for chemical cauterization.

Two of my patients suffering from the macroform have been relieved (one was treated 8 years ago, the other 3 years ago) by removing all loose epithelium, lightly scraping the cornea, and applying 10-percent trichloroacetic acid. In one a very faint corneal haze resulted, which

did not interfere with vision. In the other there was no opacity. In the microform, I should like to emphasize the dramatic relief obtained by putting 10-percent boric ointment in the eye at bedtime, and cautioning the patient about using care when first opening the eyes after sleep. After using the ointment every night for a period of a few weeks some patients are apparently permanently relieved. In others, after a period of one or several months without treatment, the attacks may commence again, but it is a great satisfaction to the patient to feel that he has at hand a simple remedy which, if it does not always permanently cure the disorder, will at least eliminate the symptoms while it is being used. Whether or not the nightly use of boric ointment will prevent attacks in the macroform I have not determined. In this form the attacks as a rule come months or years apart, and few patients will consent to putting ointment in the eyes for such a long period when they are without symptoms.

SUMMARY AND CONCLUSIONS

1. From a clinical standpoint, two forms of recurrent erosion can be recognized, the macro- and the microform. In the macroform the corneal lesion is relatively large, the symptoms are prolonged and severe, and attacks occur as a rule

at long intervals. In the microform the lesion is small, usually 1 to 2 mm. in diameter, the symptoms are mild and of short duration, and the attacks come at frequent intervals.

2. The microform is apparently three or four times as common as the macroform.

3. Careful exploration of the cornea in a dark room with the ophthalmoscope, using a +4.00 lens, is a practical method of detecting the corneal lesion in the microform.

4. A damaged endothelium may be the cause of the persistent epithelial edema.

5. The occurrence of the attacks at night or on first waking from sleep may be due not only to the trauma incident to opening the eyes, but also to increased epithelial edema at this time from a relative hypotonicity of the tears overlying the cornea.

6. For treatment of the microform it is recommended that an ointment (10-percent boric) be put in the eye at night, and that the patient be instructed to use care in opening the eyes after sleep. For the macroform apparently the most effective treatment is removal of all loose epithelium, scraping the cornea, and chemical cauterization of the denuded area.

ELECTRICAL SENSITIVITY OF THE EYE IN SOME OPTIC-NERVE DISEASES RESULTING FROM CRANIO-CEREBRAL TRAUMATA*

S. V. KRAVKOV, M.D. AND A. N. MURSIN, M.D.

Moscow, U.S.S.R.

Penetrating wounds of the brain frequently cause intracranial infection and involve changes in the ophthalmoscopic picture of the fundus; namely, papilledema. The nature of the edema is varied. Sometimes it is caused by a stasis of the fluid of the optic nerve (choked disc) and in some instances it is the result of an inflammatory process in the nerve (neuritis).

According to ophthalmologists it is often difficult to decide, on the basis of the ophthalmoscopic picture only, whether the papilledema is the result of an in-

flammatory or of a noninflammatory process. Blurred disc margins, hyperemia (congestion), bulging of the disc, disproportion in the diameter of veins and arteries do not seem definite enough to allow of a proper initial differential diagnosis. Axenfeld,¹ for example, has stated: "If the inflammatory focus in the optic nerve is situated somewhat posteriorly to the disc, the latter is simply involved in the process owing to collateral edema. To differentiate a choked or an inflammatory disc is quite embarrassing in this case." The degree of elevation of the swollen tissue is no reliable criterion because of the absence of more or less considerable edema in the early stages of genuine choked disc, and further: "If no functional disturbances are present, optic-nerve inflammation in its early stages is apt to remain undetected." A well-established differential diagnosis, on the other hand, is of great value in indicating proper treatment.

* From the Laboratory for Physiological Optics of the Central Helmholtz Institute of Ophthalmology (Moscow) Director of the Laboratory Prof. S. V. Kravkov and Director of the Institute-Academician M. J. Averbach, and from the Kazan Institute for Trachoma Diseases, Director-Honored Worker of Science Prof. A. N. Mursin.

Because of transportation difficulties it has been impossible to get a corrected proof from the authors.

EXPERIMENTAL

In order to help in solving this difficult problem we attempted a method of differential diagnosis between choked disc and optic neurosis, based on the determination of the electrical sensitivity of the eye. It seems probable that the electrical sensitivity of the eye may reflect the deep-seated retrobulbar changes of

rent giving rise to a phosphene, the patient had his head covered with an opaque black cloth. The determination was first performed on eyes adapted to light and later on eyes adapted to darkness after the patient had been sitting for 6 to 7 minutes with his head covered with a black cloth and his eyes closed; then once again on the light-adapted eyes

Fig. 1 (Kravkov and Mursin). Scheme of the arrangement for measuring electrical sensitivity of the eye.

the visual apparatus. This investigation was carried out in 1941-1942 in two base hospitals in Kazan.

Method. A routine apparatus was used to determine the threshold current giving rise to an electrical phosphene (rheobase). The scheme is represented in figure 1, in which n_1 , n_2 are the wires attached to the source of the current; R , the resistor, is switched on as a potentiometer; E_1 , E_2 are silver electrodes placed on the hand and on the eye of the patient; S is a slide running through the wire of the resistor, R ; A is a microammeter; K is a key for switching on and disconnecting the circuit.

The test was performed in a lighted room, usually in the morning. During the determination of the threshold cur-

after these had been open for 5 to 7 minutes in a lighted room. Thus, the method enabled us to determine the level of the electrical sensitivity of the patient's eye as well as its adaptation changes as these occurred during the transition from light to darkness and inversely. Unfortunately, we were unable to standardize the brightness of the light used for adaptation; however, there have been no significant differences in the level of this brightness.

The data obtained in our experiments are presented graphically. Periods of light and dark adaptation of equal duration (see figs. 2 to 5) are marked on the abscissa; values of the threshold current measured in 10^{-5} A (ampères) are marked on the ordinate, L being the

period of light and D that of dark adaptation.

Our observations cover 35 cases of cranio-cerebral traumata. In many instances electrical sensitivity of a patient's

eye was measured twice, thrice, and even oftener, these measurements having been repeatedly carried out over a period of some months. In addition, the electrical sensitivity of a control group of six

healthy persons with a normal organ of sight was investigated under the same conditions as obtained in the test. Three patients who had undergone an enucleation of the eye for a traumatic iridocyclitis have also been tested. We were anxious to find out in what proportions the adaptation changes were preserved in the stump of the enucleated eye.

The ophthalmoscopic diagnosis was

had been ophthalmoscopically made, the threshold of electrical sensitivity was found to be between $18 \cdot 10^{-5}A$ and $60 \cdot 10^{-5}A$. In cases wherein disc congestions and other changes of a neuritic nature in the fundus were present we observed, as a rule, a still more significant decrease in electrical sensitivity. In five such patients the threshold value varied from $22 \cdot 10^{-5}A$ to $160 \cdot 10^{-5}A$. It is to be

Fig. 2 (Kravkov and Mursin). Adaptation changes of the threshold current in the cases of choked disc.

established by one of us (A. N. M.). Table 1 contains brief data on the nature of the injury we had to deal with and on the ophthalmoscopic fundus condition. These data are shown in columns 2 and 3.

Results. The results of all the tests performed allow the following conclusions to be drawn:

1. Electrical sensitivity of the eye is decreased in the case of a choked disc as well as in neuritic changes in the fundus.

Thus the threshold of electrical sensitivity in patients with a normal organ of sight (having never undergone this kind of test) varied under light conditions between $8 \cdot 10^{-5}A$ and $18 \cdot 10^{-5}A$. In six patients whose diagnosis of choked disc

noted that we had the opportunity to observe certain cases wherein a diagnosis of choked disc and neuritic hyperemia had been made; nevertheless the threshold value of the current remained almost as high as in the controls (inexperienced in this kind of test). It may very well be that in these cases the level of electrical sensitivity of the patient's eyes was still decreased, the threshold value being higher than under normal conditions in the same individuals.

2. In cases of papilledema of non-inflammatory nature the normal picture of adaptation changes of the electrical sensitivity of the eye is preserved; that is, under dark conditions the threshold value

increases, and, inversely, under light conditions it falls—that is, the sensitivity rises (fig. 2).

3. Abnormal adaptation changes in electrical sensitivity of the eye are char-

curred in all cases suggestive of optic neuritis.

Thus, the data obtained lend some support to the statement that the measurement of adaptation changes of the

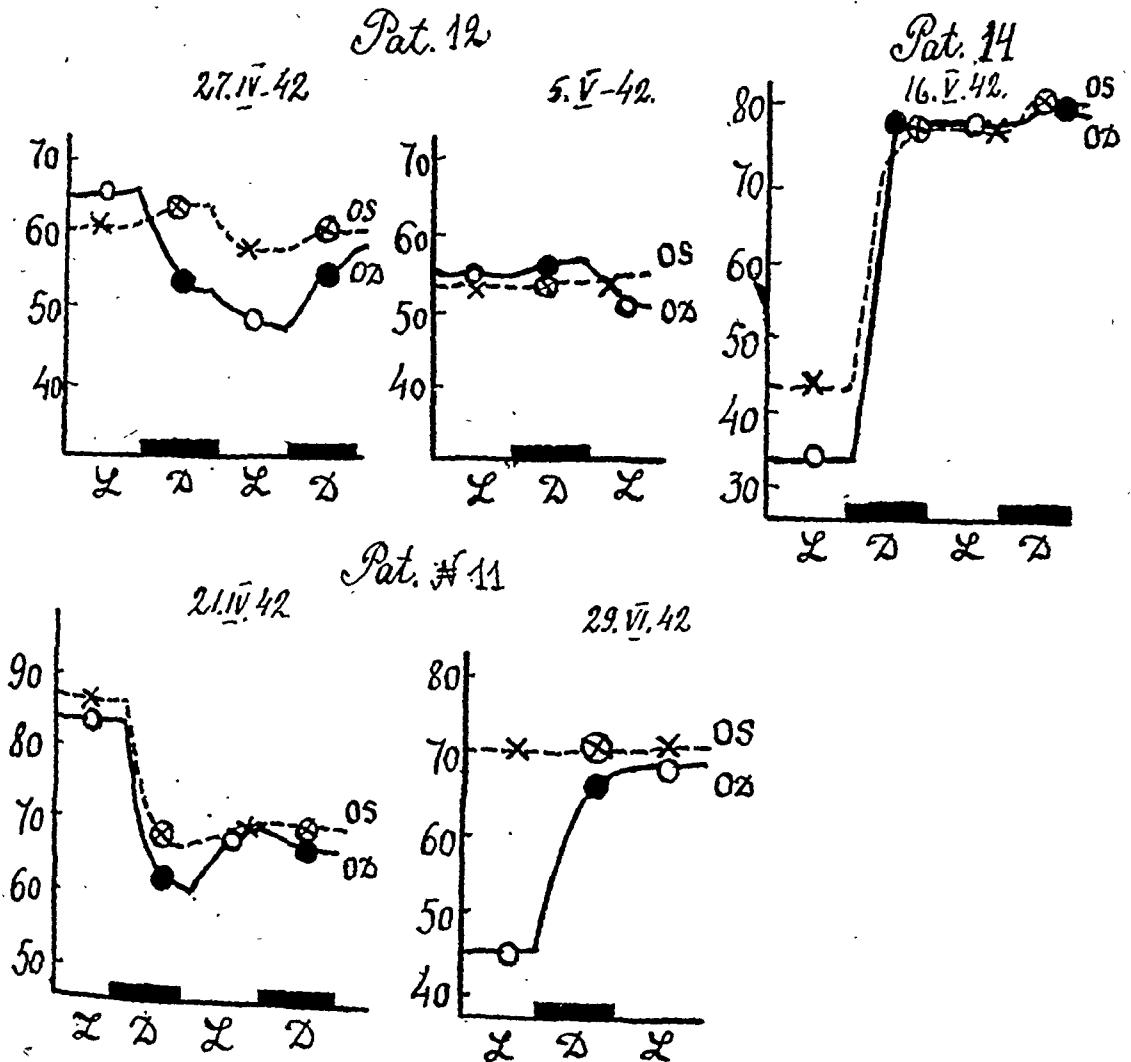

Fig. 3 (Kravkov and Mursin). Adaptation changes of the threshold current in the cases of optic neuritis.

acteristic of patients presenting neuritic alterations in the optic nerve, and of those whose case history is suggestive of such alterations. Electrical sensitivity remains almost unchanged or shows abnormal changes in these cases under transition from light to darkness and inversely.

Figure 3 shows some typical pictures of such adaptation disturbances. They oc-

cur in all cases suggestive of optic neuritis. Thus, the data obtained lend some support to the statement that the measurement of adaptation changes of the electrical sensitivity of the eye is a rather helpful method for establishing a differential diagnosis between inflammatory and noninflammatory papilledema. The adaptation changes in the electrical sensitivity of the eye may be presented quantitatively by the ratio D/L where D is the threshold intensity of the current, under dark adaptation and L the threshold intensity

of the current under light adaptation.

The ratio D/L has been calculated in all the cases we investigated. The values are shown in column 5 of table 1.

It will be seen that in the presence of neuritic changes in the optic nerve the ratio D/L is comparatively small and frequently approaches 1. It is to be noted here that the average value of D/L , calculated from the results yielded by all our experiments in normal cases under

changes under dark and light conditions of the other eye, even if the electrode is applied to the stump of an enucleated eye confirms this assumption. The adaptation changes in the electrical sensitivity of the stump of an enucleated eye has been previously described by Akimotchkina, Bogoslovski, and Ivanova.² Their finding was corroborated by us in connection with the present paper (see our data on figure 4).

Fig. 4 (Kravkov and Mursin). Adaptation changes of the threshold current in the stump of an enucleated eye.

the same test conditions, has been 1.87—thus, greater than in all the cases of cerebrocranial injuries we investigated.

4. Disturbances of the adaptation in the electrical sensitivity of the eye may rather denote retrobulbar processes taking place in regions situated more centrally from the eyeball.

The maintenance of normal adaptation

The threshold values of the current for the stump of an enucleated eye are marked in figure 4 by a broken line; those for the normal (control) eye, by a solid line.

5 The determination of the electrical sensitivity of the eye is a rather helpful method for the clinician, frequently revealing abnormalities in cases wherein

the ophthalmoscopic picture of the fundus seems to be normal.

Thus, for example, in one case (patient 24), the changes in electrical sensitivity of the eye prognosticated atrophic changes in the disc. In another case (patient 6), where there had been a wound in the right parietal region and a left-sided hemiplegia, we were able to detect a considerable decrease of the electrical sensitivity of the left eye, although the

later, the electrical sensitivity of the eye became decreased again, although the ophthalmoscopic picture remained normal. A month later the condition of the patient became worse.

In some cases we have found a somewhat close correspondence between the picture seen ophthalmoscopically and the data obtained by the measurements of the electrical sensitivity of the eye (see, for example, figure 5).

Fig. 5 (Kravkov and Mursin). Abnormal adaptation changes of the threshold current paralleling the anomalies seen ophthalmoscopically.

ophthalmoscopic picture of this eye proved to be normal. In patient 14, wounded in the occipital region by a shell fragment, ophthalmoscopy at first showed no abnormality in the fundus. Meanwhile, the electrical sensitivity of the eye had decreased and its adaptation changes disturbed. A brain abscess was soon diagnosed and drained. (The fundus now shows a choked disc of the neuritic type.) The determination of electrical sensitivity of the eye, made after the patient had recovered, showed considerable improvement, though the electrical sensitivity had not reached its normal level. Some days

Patient 21 showed a noticeable disturbance of the adaptation in the electrical sensitivity of his right eye. The electrical sensitivity of the left eye of patient 35 was considerably worse than that of his right eye. Correspondingly, ophthalmoscopy disclosed in the case of patient 21 a normal condition in the left eye and a hyperemic disc in the right eye; in patient 35 ophthalmoscopy revealed a descending optic-nerve atrophy in the left eye and a normal fundus in the other.

IMPROVED TREATMENT FOR CHEMICAL BURNS OF THE EYE

L. WESTON OAKS, M.D.

Provo, Utah

There are few injuries of the eye more serious, and before which the physician is more helpless, than are severe chemical burns. Such accidents moreover, are not so rare as they should be, in industry or elsewhere.

For the relief of these cases, published thought seems to occupy itself with: (1) copious irrigation with water;^{1, 2, 3, 4, 5, 6, 7} (2) neutralization of reagents causing injury;^{2, 3, 5, 6, 8} and (3) prevention or correction of scarring from the burns of lids, conjunctiva, and globe. The writer discovered only two instances of therapeutic intervention leading beyond these methods. Value of such basic principles is in no way to be discounted, but they do frequently fall short of meeting needs of a specific problem. Any modification or addition which will increase the average of good results in these emergencies seems worthy of publication.

Neuman⁹ dealt with immediate transplantation of mucous-membrane grafts to cover necrosed areas of conjunctiva, and was quite convinced of its great value, both as to speed of recovery and as to improvement of end results. With this the writer has had no considerable experience.

Pichler¹⁰ and Middleton² brought out the great helpfulness of corneal paracentesis in saving eyes burned by ammonia. Application of this procedure to other ocular burns of serious degree, with encouraging results, appeared to justify some testimony as to its usefulness.

In their writings, the aforementioned writers maintain that this is the only way to prevent loss of an eye damaged by ammonia. They state that the method

helps by liberating aqueous which is loaded with ammonia that has permeated corneal tissues, thus freeing the iris from destructive effects of the poison upon it. Walter Kies¹¹ has described well the changes that take place in ocular tissues from action of ammonia upon the globe. His description bears out the belief of others that this alkali does rapidly find its way into the aqueous.

Since this is true of ammonia, it appears not unlikely that other powerful chemicals may act upon the eye in a similar fashion. The present writer was particularly impressed that this might be true of most alkalis. Brief case narrations may serve best to illustrate results achieved by paracentesis and repeated drainage in cases of several types.

CASE REPORTS

On December 27, 1937, a boy, aged 16 years, was brought in because of burns about the face and eyes from the explosion of a carbide tank near which he was working. Force of the explosion rendered him unconscious momentarily. Conjunctiva and lids of the left eye were burned, and the cornea was densely white, except for a margin about 2 mm. wide, at the limbus above. Copious irrigation with water had already been carried out.

The anterior chamber was opened at once with a keratome. Escaping aqueous was opalescent and appeared to be under abnormal pressure. For one week, daily drainage was done by depressing one lip of the wound with a spatula. Aqueous fluid was macroscopically transparent after the second opening.

By January 5th, this cornea had cleared

sufficiently to permit visualization of the iris, and of a traumatic cataract which appeared to have resulted from the force of the explosion. Corneal clearing progressed until, at the end of four months, only slight general haziness remained. Had I at that time been familiar with the use of ammonium chloride or tartrate in this connection, the remaining haziness might have been erased, for it was learned that lime made up one of the chief ingredients of this particular carbide mixture.

On April 5, 1941, a child, aged 2 years, was hurried from a town 90 miles away, because of lye burns of the face and eyes. His family physician had irrigated the injured eye freely with water about one hour after the accident.

The child's face was covered with corrosive burns of varying degree and extent. His lower lip was greatly swollen, and much of its mucosa gone. The caustic solution had more or less saturated his clothing over the left deltoid area, and a large patch of skin there was entirely destroyed. His right eye had escaped, but the left showed whitened conjunctiva of lids and globe, and a cornea that was "milk white" and opaque, except for a narrow crescent adjacent to the superior limbus.

Paracentesis of the cornea was speedily accomplished, and hospitalization begun. Eight hours later, the wound was reopened with a spatula, thereby again liberating a quantity of opalescent aqueous. In another 13 hours the drainage was repeated, and the eye looked appreciably better. Twice each day the wound was reopened for three days. Then intraocular pressure remained normal to palpation, and the drainage was carried out only once a day for another four days, at the end of which time it was discontinued.

The upper two thirds of the cornea became rapidly transparent to macroscopic observation, and the iris had a normal appearance.

Three months later, there was a leucoma occupying a lower section of the cornea, extending from the 5- to the 7-o'clock position at the limbus and to a little above the center. The iris still appeared normal, and there was no evidence of degenerative changes in the globe, except for the leucoma, and the intraocular pressure, which was 26 mm. (Schiøtz). So far as the writer knows, this patient still retains his eye and has had no further trouble with it. At that time he was too young to give me a satisfactory idea of his vision, or of the visual field remaining. Results in this case, considering that several hours had elapsed before he reached me, and in view of the severity of the burns, were striking. Certainly, from all therapy usually advocated for these cases one had no right to expect anything more than an atrophic stump.

Sometime after the experience with this second case, there came under observation, a young man whose wife instilled beechwood creosote into his left eye, thinking she was using a collyrium he had requested. When first seen, this patient was in great pain, and there was obvious destructive action of mild extent upon the conjunctiva of the lower eyelid. The cornea presented no visible haziness, although there was some loss of surface tissue. The usual treatment for such burns was instituted but gave little relief. In 48 hours pain actually seemed more severe, intraocular pressure was definitely increased, and there was evidence of uveitis. Corneal paracentesis was performed. Following the immediate period of acute agony from this operation, this man slept for the first time since his injury.

Daily drainage was carried out for four days. The eye rapidly recovered, and no visible damage remained from the accident; visual acuity was 20/14.

These several cases may serve to emphasize the fact that something more effective may be done for chemical burns of the eye, whether they be mild or of serious degree. Naturally, the outlook in any severe case is infinitely better if the procedure can be carried out in the first hour or two after injury. However, the method still seems to promise much help, even after this lapse of time, and especially in regard to relief of pain and tension.

The high favor in which S. R. Gifford and his father before him held corneal section for the relief of advancing ulcers may not be entirely without significance in this particular. Perhaps other helpful effects are achieved, besides liberation of chemical toxins which have become mixed with aqueous, and freeing uveal tissues of their destructive action. Relief of pressure upon the greatly swollen corneal tissues must surely promote better circulation of fluid through their lymph spaces, to lessen necrosing influences. The surprising relief obtained from agonizing pain, in most of these patients, is itself sufficient evidence of alleviation.

The most impressive tissue changes are seen in the cases of burns due to lime and to lye, in which the cornea is almost immediately white from the effect of the caustic. Here, it should be emphasized, drainage must be instituted just as soon as possible. Every minute of delay represents lost chances of recovery. In these severe injuries, drainage twice daily should be kept up for several days, then once each day for three to five days longer.

The method of performing the paracentesis with a bevelled plane has been clearly described by many others and need not be repeated here. Successive openings are readily accomplished with a thin surgical eye spatula, and repeated incision is rarely necessary, unless a longer period than 24 hours elapses between treatments. Aqueous is allowed to escape slowly until the anterior chamber's apparent depth is diminished by one half to two thirds.

Most writers are specific in differentiating, as to therapy, between burns from acids and those from strong alkalis. Perhaps the method of attack upon tissues of the globe does differ chemically with each, but there is no proof as yet that the same harmful influences are not set in motion by both of these agents of tissue destruction. Response to surgical treatment suggests that the same underlying principles may be operative through all such agents of injury. Similar favorable experience with a severe gasoline burn of conjunctiva and cornea, coming after a series of experiences such as those afordescribed, has led the writer to believe that paracentesis of the cornea should be established as a standard procedure for every moderate or severe burn of the cornea where any tissue destruction or haziness results, irrespective of the chemical involved.

Such a broad statement might properly lead one to inquire concerning the use of this method in the treatment of war-gas injuries of the eyes. Many characteristic pathologic results therefrom suggest chemical burns in slow motion, as it were. Certainly few of us have had any opportunity to observe these lesions in private practice, but this problem should readily lend itself to study through animal experimentation.

VISUAL SYMPTOMS CAUSED BY DIGITALIS*

FRANK D. CARROLL, M.D.

New York

The purpose of this paper is to report the visual symptoms that occurred in six patients who were taking digitalis. In three, general symptoms of digitalis intoxication caused the patients to return to the internist for advice but the other three came directly to me because of visual disturbances. None of these suspected digitalis as the cause and none gave me a history of taking digitalis until they were specifically questioned regarding it. These three showed no other signs nor symptoms of digitalis intoxication except for the visual complaints and so it was natural for them to consult an ophthalmologist rather than the physician who had described the cardiac drug.

That digitalis may cause visual disturbances has been known for at least 159 years. In 1785 William Withering¹ in his

classical paper on the foxglove stated that when given in large doses, it might result in "confused vision, objects appearing green or yellow. Although the general literature contains numerous references² to this subject, very little concerning this condition could be found in the American ophthalmological literature.³ Paul D. White, the prominent Boston cardiologist, recently stated⁴ that he sees "several such patients a year who had just enough oversaturation with digitalis to have developed these eye symptoms," but he feels "quite sure that the average doctor does not inquire about them." In speaking with internists I received the impression that the condition is not well known to them and I think it is even less well known to ophthalmologists.

The general symptoms are usually much more prominent than the visual disturbances. The most common^{2,5} are anorexia, nausea and vomiting, and occasionally diarrhea. These symptoms are not due to any effect on the gastrointestinal tract but are central in origin—just as the

* From the Department of Ophthalmology, College of Physicians and Surgeons, Columbia University, and the Institute of Ophthalmology, Presbyterian Hospital. Presented at the eightieth annual meeting of the American Ophthalmological Society at Hot Springs, Virginia, in June, 1944.

eye symptoms are probably central in origin. There may be marked slowing of the heart rate and the electrocardiogram may show a characteristic graph. The central nervous system infrequently reacts by depression or excitement, headache, impairment of memory, confusion, or delirium.⁶

The visual symptoms of the patients seen by me were as follows (table 1): Two stated that snow seemed to cover everything at which they looked. My face

The white vision of which two of these patients complained is mentioned in the literature. One man,⁷ on looking from his hospital window, saw white automobiles travelling along the street. His daughter, dressed in a dark-blue coat, came to visit him, and he asked her when she had obtained her white coat. He then thanked her for the white flowers she had brought him—they were actually red tulips. The colored vision may also be green, blue, yellow, or red. Flickering and flashing

TABLE 1
DATA ON VISUAL DISTURBANCE FROM DIGITALIS

Name	Sex	Age	Dose—Powdered-Leaf Tablet Form	Symptoms	Vision	Eye Pathology
U. N.	F	42	Maintenance dose 0.1 gm. daily	Snow on everything	20/20 O.U.	None
J. L.	M	43	0.3 gm. daily—3 gm. in 10 days	White and yellow snow	20/20 O.U.	None
J. B.	F	75	Maintenance dose 0.1 gm. daily	Bright shiny spots, sees "diamonds"	20/100 3/200	Diabetic retinopathy, lens opacities
J. F.	F	85	0.2 gm. daily for 30 days followed by 0.3 gm. for 2 days	"Nearly blind," flashing lights, nausea	20/70 O.U.	Lens and vitreous opacities
D. K.	M	33	4.4 gm. in 10 days (Pt. weighed 275 lbs.)	Red and green spots, nausea	20/20 O.U.	None
H. M.	F	41	0.4 gm. daily for 7-9 days	"Black lines," "glare," green vision, nausea, vomiting	20/20 O.U.	None

seemed to have snow on it. One colored man said my face appeared covered with "sulphur" or "yellow snow." When he closed his lids he saw yellow flowers dangling in front of his eyes. One woman saw bright shiny objects which looked like gold fish and complained of lights flickering. Another saw bright and dark spots. A physician who before taking digitalis noticed black specks floating before his eyes complained that these specks had turned to red and green spots. He said that he had always had *muscae volitantes* but they became colored after taking large doses of digitalis. The sixth patient said everything was green. She stayed in a dark room because of the "glary brightness."

of light are said to be early symptoms.² Purkinje⁸ in 1825 experimented on himself, and noticed light flashes, flickering, and flowerlike figures in the center of his visual field.

This condition frequently recurs. One of the aforementioned patients had a previous attack of green vision associated with nausea and vomiting. She judged her recovery by looking at the apparent color of her skin. After the drug was stopped for a few days she said that at times her skin appeared normal in color, at other times it still seemed green. Jackson⁹ reported a case of yellow vision which cleared up spontaneously in five weeks, reappeared a year later for eight weeks, and upon recurrence in a third attack was

accompanied by such general disturbances that hospitalization was sought and the true nature of the visual disturbances finally discovered.

The visual acuity, fields, and fundi of the patients seen by me were unaffected by the digitalis when I examined them. Despite all the symptoms mentioned there was nothing to be found objectively. One patient stated that during a previous attack she had lost the sight in one eye and had been unable to read with that eye. Jackson⁹ wrote that his patient was unable to read the largest type in the newspaper but nine days after discontinuing the drug "she could read the finest print." He states that at times she had double vision and often the right side of an object disappeared before her eyes. Smith⁶ mentioned blurring of vision, scotoma, diplopia, and colored vision. One report² by a cardiologist describes a patient receiving digitalis in normal doses who developed "almost complete blindness"—ophthalmologists could find nothing wrong—finally the possibility of digitalis amblyopia was considered, the drug was stopped and the sight returned completely. Another article¹⁰ mentions a temporary complete blindness as well as an amaurosis which lasted three days.

How are we to interpret these reports? The most likely interpretation to me seems to be this: Digitalis acts on the central nervous system, it stimulates centers in the medulla which cause nausea and vomiting, it probably involves the cerebrum, causing visual hallucinations. The colored vision is really a hallucination. The confused vision is due to central functional impairment which, in turn, is due to the drug. Colored positive scotomas were present in one of my cases and are mentioned in the literature. Sometimes, as mentioned, there is some mental impairment, but my patients knew they were perceiving something that did

not exist. The temporary complete blindness mentioned in the literature probably was due to cerebral intoxication; that is, a cortical type of blindness was induced which disappeared on stopping the drug.

The dose of digitalis required to produce visual symptoms is variable. Two of my patients were on what is considered a normal maintenance dose (table 1). They were receiving $1\frac{1}{2}$ grs. (0.1 gm.) daily of the powdered leaf—that is, 1 cat unit, which is approximately the amount utilized daily.¹¹ They had no other signs nor symptoms due to the digitalis except the visual disturbances. The other patients received larger doses. This was sometimes the fault of the patient, who misunderstood the physician's directions, and sometimes it was the fault of the internist. All received the dry powdered leaf in tablet form made by reputable pharmaceutical companies. The exact component in the drug responsible for visual symptoms is unknown, but the most refined preparations may produce these symptoms as well as the crude preparations used many years ago. It does seem important to know, however, that on the dosage recommended in leading textbooks on cardiology¹¹ a patient may, infrequently, develop visual disturbances without any other symptoms.¹² These patients usually can take smaller doses without difficulty. Recovery from the visual symptoms after stopping the drug took from 3 to 7 days in my cases but it may take as long as 14 days.¹³ Overdosage has resulted in death,¹⁴ but apparently if the patient recovers the vision recovers, and I have so far been unable to find any convincing report¹⁰ of permanent visual impairment. The only treatment usually necessary is to stop the drug—the forcing of fluids may be desirable but should probably be prescribed by the physician in charge of the patient's cardiac condition.

The diagnosis may not always be easy. One of the author's patients who complained of black floating specks and bright shiny spots had vitreous opacities and a diabetic retinopathy which was thought to be sufficient to explain her symptoms. However, when she discontinued her normal maintenance dosage of digitalis the annoying bright spots disappeared, leaving only the others to which she had long been accustomed. She is able to take about half the average dosage without developing symptoms. Another elderly patient with lens and vitreous opacities complained of black streaks and flashing lights. It was only by stopping the drug temporarily and having these symptoms disappear that the diagnosis was made certain. Usually, however, if the possibility of this condition is kept in mind there will be little difficulty in making the diagnosis.

SUMMARY

This is a report of six patients who had visual symptoms due to digitalis. These consisted in colored vision—chiefly white, green, yellow, or red—flashes of light,

positive colored scotomas, and other visual hallucinations. There was no change in the visual acuity or fields of these patients, but the literature suggests that if the intoxication is sufficiently profound a temporary cortical type of blindness may result. This condition may occur in patients receiving what is considered a normal dosage of the drug and may be the only symptom present. Recovery takes place within two weeks after stopping the digitalis.*

635 West One Hundred Sixty-fifth Street (32).

* Since presenting this paper the author has, in routine office and clinic practice, observed six more patients with visual symptoms due to digitalis, making a total of 12 such patients seen by him. Visual complaints included "the sensation of looking through water," "colored streaks and stars," "blue flowers," "serpents," "yellow and red spots," "ornaments," white vision, and shimmering lights. All these symptoms vanished within a week when the dose of digitalis was decreased even though several of these people were on a so-called "maintenance dose" of 0.1 gm. daily. There is a tremendous variation in the dose necessary and tolerated by cardiac patients. Each person's dose is an individual problem. It is obvious that visual symptoms are not infrequent.

COMPLETE CONGENITAL PIGMENTATION OF THE OPTIC DISC

WALTER MOEHLE, M.D.

Brooklyn, New York

Congenital pigmentation of the optic disc is of comparatively rare occurrence, and references to it in the literature are infrequent. While several types of pigmentation have been recognized, few cases of entire pigmentation of the papilla have been reported. Sobánski observed a case of complete pigmentation of the disc. From a survey of the literature he found only two cases which he believed to be similar. Hirschberg described a color of uniform dark slate gray upon which the retinal vessels were scarcely visible. Forster referred to the pigmentation of the disc as shades of dark smoked glasses. These men were of the opinion that the condition was a congenital anomaly—a melanosis of the optic nerve.

Juler and Mann referred to three main types: (1) Dense isolated plaques which might occupy a sector of the disc and extend into the surrounding retina. These might appear black with otherwise normal eyes, or might be confined to the physiologic cup and be brownish gray in color. (2) As linear markings, commonly found on the temporal side near the disc edge, and curved concentrically with it. (3) As lacelike pigmented veils, closely associated with the blood vessels.

Thomson and Ballantyne reported a case of pigmented colobomata of the optic disc in a myopic patient in whom both discs presented an unusual picture. The appearance of the right disc was as if a wedge had been cut out of its outer and lower portion. This colobomalike wedge contained a network of brown pigment situated below the level of the disc surface. In the left eye, the pigmentation was similar, but instead of extending to the very edge of the disc it was separated from it by a narrow band of nerve tissue.

Reese mentioned small, isolated, clearly demarcated dots of jet-black pigment located superficially in the nerve-fiber layer of the disc. Small pigmented spots do not appear to be rare. Ogawa observed seven cases of this type in which the pigment was distributed indiscriminately over the disc. He believed that these spots are not necessarily associated with any other abnormal pigmentation of the eyeball and that they do not interfere with vision. Of an allied nature are rare instances of pigmentation of the entire disc.

Coats, in describing two classes of congenital pigmentation, was of the opinion that the isolated black spots are due to a pigmented lamina cribrosa. His second group comprised pigmented craterlike holes in the disc. The same author advanced the hypothesis that in certain groups of congenital anomalies, any part of the secondary vesicle and optic stalk may differentiate, perfectly or imperfectly, into any type of tissue normally from the optic outgrowth; for example, pigmented epithelium, unpigmented epithelium, retina, or neuroglia. These might occur in the following situations: (1) on the iris, (2) on the ciliary body, (3) on the retina, and (4) on the optic nerve. Consequently, it should be possible to find any of these four kinds of tissue in the optic nerve or in the eye proper. From these observations the idea may be advanced that, in congenitally abnormal eyes, a part of one layer of the secondary optic vesicle can develop into structures which normally originate in the other, or in a different part of the same eye.

Roll described a case of congenital pigmentation of the optic disc complicated with retinitis diabetica. The vision was reduced as a result of the macular exu-

dates and hemorrhages. The left eye had a visual acuity of 6/9 uncorrected. The optic disc appeared normal in outline with its contour uniformly black, contrasting with the surrounding fundus. He believed it to be congenital because of the even distribution of the color of the disc.

Goldenburg reported a case of anomalous optic nerve head in both eyes of a Negro. Corrected vision in the right eye was 20/40, and in the left, 20/25. Ex-

Fig. 1 (Moehle). Complete congenital pigmentation of the optic disc.

amination of both fundi revealed an unusual anomaly. The nerve head could not be differentiated, but there appeared to be a marked and intense pigmentation in the region of the nerve head which gradually became lighter toward the periphery. The disc margins could not be made out, and the retina showed a diffuse and light pigmentation. The fields were contracted to 20 degrees up, in, and down, and 50 degrees out.

Neuper reported the case of a woman 20 years of age who complained of a "burning back of the eyes." The vision in the right eye was 20/20, and in the left, 20/40. The disc of the left eye showed a

complete and very distinct ring of pigment. The picture in the right eye was similar, but to a lesser degree. The eye grounds showed old inflammation, but no pigmentation.

Zentmayer described the case of a Negress, 27 years old, who complained of asthenopia, pain in the right side of the head, and recurrent styes. In the right eye there was a small vacuole in the lens. The papilla was oval, axis 95 degrees, with a large excavation involving four fifths of its surface. Within the excavation on the temporal side, a dark-gray crescent was present. The pigment seemed to be on the outer wall of the excavation. Contiguous with this, outside of the excavation, which extended to the scleral ring, there was a cone of the same tint. The picture in the left eye was identical.

Recently, Kravitz reported three cases of partial pigmentation of the optic disc; in all, the vision was correctable to 20/20. The fundi were entirely normal except that the temporal disc quadrants revealed slate-colored pigmentation. In each case he referred to a cilioretinal artery, but could not explain its significance. The fields showed no defects; neither holes nor colobomas were present in the pigmented area.

Undoubtedly the greater percentage of these pigmented discs are discovered through the routine examination of the fundus. It is most unusual for them to cause any disturbance in vision or to change in appearance during a period of observation. The case to be presented occurred in a patient who entered the Kings County Hospital Eye Clinic. Chronic glaucoma was present in the left eye. The pigmented disc in the right eye was discovered during routine fundus examination. This patient has been under treatment for chronic glaucoma of the left eye since January 9, 1939. During this interval, the pigmented papilla has not

changed in appearance, and has remained consistently confined to the disc proper. There has been no change in the visual acuity.

CASE REPORT

M. M., a man, aged 65 years, came to the eye clinic on January 9, 1939, with a history of poor vision in the left eye. A diagnosis was made of chronic glaucoma, which was controlled for a time with pilocarpine hydrochlorate. He was admitted to the Hospital on January 15, 1939, and an Elliot trephining was performed on January 18, 1939. This failed to control the tension or to improve the vision. Later, a cyclodialysis controlled the tension, but not the vision, which subsequently became nil.

Examination revealed bilateral weakness of the lid levators. Extraocular movements were normal; tension to the fingers was increased in the left eye, normal in the right. The left eye showed iris atrophy and posterior synechia at the 6-o'clock position. There was deep excavation of the disc of the left eye, with vessels bending over the edge. The disc was nonpigmented. The right eye showed a papilla with brownish-black pigmentation which was not elevated, but was distributed over the entire disc, covering some of the retinal vessels. In the upper and temporal quadrants, dense granules

ranged to plaquelike areas of pigmentation. At no time has the vision in this right eye gone below 20/30; the best vision was 20/20 uncorrected. Refractive error of the right eye, plus two diopters. The tension in the right eye has varied from 17 mm. Hg to 25 mm., but at no time has it gone above 25 mm. (Schj  tz).

Laboratory findings: Urinalysis negative; Wassermann test negative. Blood chemistry: urea, 27 mg. per 100 c.c. of blood; blood sugar, 76 mg. per 100 c.c. of blood. Blood pressure, 134 systolic, 84 diastolic. The chest film showed an elongation and torsion of the aortic arch. There were prominence of the bulb of the aortic arch and sclerotic changes *in situ*; also a preponderance of the left ventricular contour of the heart border and accentuation of the pulmonic markings in the mesial lung fields. The cardiac status is that of arteriosclerotic and hypertensive heart disease.

Visual fields on January 17, 1939: right eye, nasal 30 degrees below 50 degrees, temporal 58 degrees above 30 degrees. Left eye, nasal 20 degrees below 40 degrees, temporal 55 degrees above 25 degrees. From January 17 to April 14, 1939, the fields in the right eye remained constant, whereas in the left eye the fields diminished progressively to fixation.

15 Schermerhorn Street.

PENICILLIN IN THE TREATMENT OF PERFORATING OCULAR INJURIES AND IN UVEITIS*

RICHARD G. SCOBEE, CAPT. (MC), A.U.S.
Randolph Field, Texas

There are two problems in ocular therapy that are of interest to the Armed Forces. One is the treatment of perforating wounds of the globe which subsequently become infected; the other is the problem of uveitis, for the therapy of this condition to date is relatively unsatisfactory. The penicillin studies to be discussed indicate at least a partial answer to both of these problems.

PERFORATING INJURIES OF THE GLOBE

The report of Cashell¹ on penicillin treatment of an infected injured eye prompted a further investigation of the subject at the AAF School of Aviation Medicine. With regard to the treatment of these cases, Cashell advised the use of penicillin eyedrops every half hour during the first 24 hours, and, if possible, the instillation of penicillin into the anterior chamber. No mention is made of any systemic administration of penicillin, either by the intravenous or intramuscular route. It was decided to attempt experimental confirmation of Cashell's clinical results and at the same time study various methods of local administration of penicillin.

EXPERIMENTAL

Rabbits were chosen as the experimental animals, but no albinos were used, since the presence of iris pigment was considered desirable. The perforating ocular injuries were produced with a pair of small, sharp-pointed scissors with blades slightly opened. The perforations were made in clear cornea, about 2 mm. from the limbus, at the 12-o'clock position. An attempt was made to injure the lens purposely in every instance. Following the perforation, 0.05 to 0.10 c.c. of a 24-hour broth culture of a virulent strain of hemolytic *Staphylococcus aureus* was injected directly into the anterior chamber via the perforation. The chosen strain of staphylococcus was tested and found to be susceptible to penicillin. The infections thus produced in the rabbit eyes were arbitrarily divided into three categories on the basis of their clinical appearance:

1. Mild—cornea diffusely clouded but no hypopyon, and entire iris visible.
2. Moderate—cornea cloudy and hypopyon present, but iris partially visible.
3. Severe—no iris visible, either because the anterior chamber was filled with pus or because the cornea

*From the Department of Ophthalmology, AAF School of Aviation Medicine.

became completely opaque; marked chemosis and palpebral edema also present.

The following routes of penicillin administration were utilized in the following manner:

A. *Anterior-chamber lavage.* The right eye received penicillin; the left eye was used as a control. A daily paracentesis was performed with a Graefe knife and following this the anterior chamber of the right eye was lavaged with a solution containing 500 units of penicillin per cubic centimeter in 0.9-percent saline. The left eye was similarly lavaged but with 0.9-percent saline alone. Two daily instillations of 1-percent atropine solution were made in each eye.

B. *Subconjunctival injection.* The right eye received penicillin; the left eye was used as a control. Daily subconjunctival injections were made in each eye, the right eye receiving 500 units of penicillin in 0.9-percent saline whereas the left eye received only 0.9-percent saline. Both eyes received two daily instillations of 1-percent atropine solution.

C. *Eyedrops.* The right eye received penicillin; the left eye was kept as the control. Drops were instilled four times daily, a solution of 500 units of penicillin per cubic centimeter of 1.4-percent saline solution (pH 7.0 to 7.2) being used in the right eye whereas a 1.4-percent saline solution only was used in the left eye. In addition, both eyes received two daily instillations of 1-percent atropine solution.

D. *Intravenous route.* Each rabbit received two daily injections of 1,000 units of penicillin in 0.9-percent saline intravenously. In addition, both eyes received two daily instillations of 1-percent atropine solution.

E. *Intravenous route plus eyedrops.* The right eye received penicillin while the left eye served as a control. In addition

to two daily intravenous injections of 1,000 units of penicillin in 0.9-percent saline, the right eyes received drops containing 500 units of penicillin per cubic centimeter of 1.4-percent saline four times daily whereas the left eyes received only 1.4-percent saline drops four times daily. In addition 1-percent atropine was instilled into each eye twice daily.

A minimum of six rabbits was used to test each method of penicillin administration. The results were comparable in each of the four groups and only the typical results will therefore be described.

RESULTS

Anterior-chamber lavage was satisfactory in controlling only those ocular infections classified as *mild*, whereas those considered moderate and severe were not at all controlled by this method of penicillin therapy.

Subconjunctival injections of penicillin in saline were satisfactory in controlling both *mild* and *moderate* ocular infections. Not only did they not control the severe infections, but subconjunctival injections actually made the eyes worse and frequently would lead to spontaneous perforation of the globe within 36 hours. The irritant effect of subconjunctival injections of saline alone is well known, and the addition of penicillin to the solution in no wise minimized this effect.

Intravenous injections of penicillin were satisfactory in controlling only the *mild* ocular infections and did not control the moderate or severe ones at all.

Eyedrops containing penicillin were satisfactory in controlling the *mild* and *moderate* ocular infections but not the severe ones.

Penicillin eyedrops plus intravenous injections of penicillin satisfactorily controlled all *mild* and *moderate* infections as well as slightly over 50 percent of the *severe* ones (see table 1).

TABLE 1

RESULTS OF PENICILLIN THERAPY OF EXPERIMENTALLY INFECTED EYES OF RABBITS AFTER PERFORATING INJURY

Method of Treatment	Type of Infection		
	Mild	Moderate	Severe
Anterior-chamber lavage	Satisfactory	Unsatisfactory	Unsatisfactory
Subconjunctival injection	Satisfactory	Satisfactory	Unsatisfactory (even dangerous)
Eyedrops	Satisfactory	Satisfactory	Unsatisfactory
Intravenous injection	Satisfactory	Unsatisfactory	Unsatisfactory
Eyedrops and intravenous injection	Satisfactory	Satisfactory	Satisfactory (in over 50% of cases)

DISCUSSION

It is apparent from these animal experiments that no single route of penicillin administration is satisfactory in controlling all ocular infections following perforating injuries, even though the etiologic organism is susceptible to penicillin. However, the combination of penicillin eyedrops and intravenous injections of penicillin would seem to be satisfactory, since it was effective in over 50 percent of the severe ocular infections.

Certainly there can be no objection to the installation of penicillin in saline directly into the anterior chamber during the surgical repair of an ocular perforation as a prophylactic measure, nor is there any objection to adopting the same procedure at a later date. However, it is felt that no great benefit was derived except in cases of mild infections in addition to the distinctly prophylactic value. Certainly the efficacy of anterior-cham-

ber lavage cannot compare therapeutically with the benefit obtained from administering penicillin by various other routes.

Use of the subconjunctival route involves certain dangers, particularly in the hands of one not too familiar with ocular pathology. The clinical appraisal of the severity of an ocular infection may not necessarily agree with the true histopathologic picture and since this route will apparently only make a *severe* infection worse, the possible hazard to the eye becomes apparent. It would seem that a severely inflamed eye simply will not stand the added insult of a subconjunctival injection.

The combination of penicillin eyedrops plus penicillin injected intravenously would seem to be the most satisfactory method of handling all ocular infections following perforating injuries. The drops should be made up in a strength of from 250 to 500 units of penicillin per cubic

Figs. 1-8 (Scobee). Penicillin treatment of experimentally infected eyes of rabbits after ocular injury.

Figs. 1 and 2. Right (fig. 1) and left (fig. 2) eyes of a rabbit having a moderate infection. The right eye received penicillin eyedrops; the left received only saline drops.

Figs. 3 and 4. Right eye (fig. 3) with a moderate infection treated with penicillin eyedrops. The left eye (fig. 4) of the same animal received penicillin subconjunctivally; it also was a moderate infection. The clinical outcome was essentially the same.

Figs. 5 and 6. Right and left eyes of one of the control animals. Both eyes had a mild infection and the only treatment used was 1-percent atropine eyedrops.

Figs. 7 and 8. Right (fig. 7) and left (fig. 8) eyes of an animal receiving penicillin intravenously, penicillin eyedrops in the right eye, and saline drops in the left eye.

Figs. 1-8 (Scobee). See opposite page for description.

centimeter of a 1.4-percent saline solution. This saline concentration instead of the usual 0.9 percent should be used inasmuch as it is isotonic with tears and allows greater penetration of penicillin into the eye; moreover, this concentration is less irritating than any other to the ocular tissues. The pH of the drops should be regulated between 7.0 and 7.2. The addition of the cationic detergent, zephiran,² is of value despite reports that another of the wetting agents, aerosol, actually seems to inhibit the action of penicillin.

The interesting question of adequate dosage of penicillin in ocular infections arises. Cashell states: ". . . compared with the dosages required in other branches of medicine and surgery, the amount necessary for the adequate treatment of all acute ocular infections in an ophthalmic unit is small." Certainly our own experience is in complete agreement. The work of Struble and Bellows³ with regard to ocular-tissue concentrations attained after intravenous administration of penicillin tends to confirm Cashell's remarks. Also, the work of Leslie⁴ and that of Crawford and King⁵ indicate that the very frequent use of penicillin eyedrops—that is, every 30 minutes—may not be necessary, since both reports indicate a persistence of bacteriostatic concentrations of penicillin in the conjunctival sac for periods of from three to five hours after the instillation of eyedrops.

On the basis of animal experiments alone, a suggested therapeutic régime for ocular perforations of eyes which subsequently become infected is: (1) 25,000 units of penicillin in 0.9-percent saline given intravenously every 12 hours, and (2) the use of penicillin eyedrops in a strength of from 250 to 500 units of penicillin per cubic centimeter of 1.4-percent saline every four hours.

One interesting but unexplained ob-

servation in the experimental work is the fact that within certain limits, the larger perforations gave a better response to penicillin therapy than did the small ones. Another obvious fact which emerges is that the sooner penicillin therapy can be initiated following the injury, the better will be the final result.

UVEITIS

There is prevalent at the moment an idea that penicillin is of absolutely no value in the treatment of so-called nonspecific uveitis. Studies at the AAF School of Aviation Medicine carried out with the coöperation of the Randolph Field Station Hospital furnish a partial negation of this idea. In 75 percent of cases of nonspecific uveitis—that is, where no causative organisms could be discovered—penicillin seemed to have a marked effect. It should be emphasized that *in no instance was a complete cure effected with penicillin alone*. However, in the majority of cases, a marked improvement occurred in the clinical appearance of the eye within 48 to 72 hours after the initiation of penicillin therapy. This observation has been confirmed by personal communication with a number of other investigators. Cases of both anterior and posterior uveitis are in the series and it is regretted that their actual number cannot be revealed for reasons of military security.

In all cases of uveitis, the patient was first given a thorough general examination in a search for possible foci of infection. Serologic and tuberculin tests as well as any other indicated laboratory work were done. In only one case could a possible etiologic agent be uncovered. All patients received penicillin in a dosage of 25,000 units in 0.9-percent saline (2.5 c.c.) every four hours—a total of 150,000 units per day. The duration of treatment varied from 5 to 12 days.

In addition, 1-percent atropine was instilled into the involved eye three times daily. No other treatment was given.

In cases of anterior uveitis, an aqueous flare would fade away within 36 to 48

hours, freely moving cells would disappear from the aqueous, and keratic precipitates would shrink and become crenated in the same period of time. There would be a concomitant improve-

ment in visual acuity. Although 75 percent of the cases showed the marked improvement mentioned, *if the patient received nothing but systemic penicillin and atropine drops as described, relapses would invariably occur in from five to seven days.* This recurrence of the clinical signs of activity of the inflammatory process was seldom as severe as the original one but was, nevertheless, present.

answer to the problem of the therapy of uveitis, but it is our feeling that it should by all means be considered an adjunct. The results in uveitis when penicillin was used indicated that, in what have heretofore been considered cases of nonspecific origin simply because of the apparent absence of any infectious foci, nevertheless 75 percent of the inflammatory manifestations were most likely the result of

Fig. 11 (Scobee). Fundus diagram and central field of patient in figure 9 about five weeks after penicillin therapy. The lesion has been perfectly "quiet" for over two weeks. The relapse in this case occurred in the form of a mild anterior uveitis six days after the initiation of penicillin treatment.

A similar picture was found in cases of posterior uveitis or chorioretinitis. Chorioretinal exudates were observed to shrink rapidly in size, in many cases, upon systemic administration of penicillin in doses of 150,000 units per day. There was a concomitant decrease in the size of the scotomata produced by these lesions in keeping with their clinical appearance of improvement. Figures 9, 10, and 11 show the clinical course of a typical case.

Penicillin is certainly not the complete

an infectious focus, as evidenced by the response to penicillin. The fact that these cases improve on penicillin therapy seems strongly indicative of a bacterial origin rather than an allergic one, or the effect of the penicillin-resistant tubercle bacillus.

If 75 percent of patients with non-specific uveitis receive such an apparent therapeutic "boost" from the use of penicillin, and if there is no contraindication to the simultaneous administration of foreign protein, vasodilators, or

salicylates with penicillin, then certainly the patient should not be denied the possible benefits of the drug provided it is available.

SUMMARY

A study of various routes of penicillin administration in therapy of perforating injuries of eyes which subsequently become infected has been made. These include anterior-chamber lavage, subconjunctival injections, eyedrops, and intravenous injection. Of these, only a combination of the eyedrops and the intravenous route was at all satisfactory in controlling severe ocular infections. On the basis of experimental work alone,

a possible therapeutic régime in such cases is suggested.

Penicillin is not the entire answer to the therapy of uveitis; it is quite definitely an adjunct. Seventy-five percent of uveitis cases showed a marked and rapid improvement in clinical signs within 48 to 72 hours of the initiation of penicillin therapy. In no instance was a complete cure effected with penicillin alone, and if no therapy other than penicillin was employed, relapses almost invariably occurred in from five to seven days. Nevertheless it is felt that any patient with uveitis should have the benefit of this therapy if the drug is available.

CONGENITAL GLAUCOMA AND CATARACT, BILATERAL; GONIOTOMY AND NEEDLING*

CASE REPORT

THOMAS D. ALLEN, M.D.
Chicago

In December, 1921, there appeared in the *American Journal of Ophthalmology* an article by Dr. H. Gifford, of Omaha, Nebraska, in which he recounted his experience and that of his associate, Dr. James M. Patton, with the Curran peripheral iridotomy in the treatment of glaucoma. Curran had written several articles¹ explaining the new procedure and giving his explanation for the resultant beneficial effects. The technique was a slight modification of the transfixation of the iris as it is usually done for iris bombé. The modification consisted in cutting through the bridge between the two holes in the iris, thus making a tongue flap. It was "necessary to cut toward the iris base." If one cut slightly into the inner surface of the cornea it did not complicate the operation unless undue hemorrhage resulted.

As I read Dr. Gifford's article it occurred to me that the benefit occasionally achieved was probably due to cutting into the region of the canal of Schlemm and not to the iridotomy, and I so wrote Dr. Curran immediately. I talked it over with Dr. Wilder, but he did not seem impressed, and I consequently dismissed the idea. I did not, at the time, know of the De Vincenti operation.

When Dr. Otto Barkan² brought out his operation of goniotomy under direct observation my interest was kindled anew, because (1) we had begun to study the iris angle under the gonioscope, both before and after various types of

operations, and (2) it seemed to me that by this means we should obtain the advantages of iridectomy without losing aqueous. When one loses aqueous the iris comes to lie against the corneal endothelium, and disturbance of that thin layer of cells is often followed by adhesions between the iris and cornea; adhesions which usually nullify the very purpose of the operation—that is, they interfere still further with the escape of the aqueous.

I tried several times to perform the operation as nearly as I could according to Dr. Barkan's technique, but found it impossible (1) to keep fluid under the contact glass while inserting the knife, and (2) to keep the area of operation in focus. I tried then, after thorough study of the angle preoperatively, to reach the trabecular angle without using the contact glass. It seemed to me it should be no more difficult than to pass a cataract knife across a chamber; neither can be done satisfactorily across a shallow chamber. But if the chamber is normally deep, especially if by gonioscopy one can see the trabecular area, one should be able to engage that area with the point of a knife.

It was difficult to force the Knapp knife (Curran's and Gifford's suggestion) clear through to the opposite side of the chamber, owing to the fact that the Knapp knife has a conical shaft (that is, the shaft 10 mm. from the point is thicker than it is 6 mm. from the point) and in forcing it through, the eye turned and the landmarks were displaced. The same thing was true of the Barkan

* Presented at the eightieth annual meeting of the American Ophthalmological Society, at Hot Springs, Virginia, June, 1944.

goniotomy knife, which otherwise seemed perfect. However, in several cases satisfactory results were obtained which have been permanent. Some of these have already been reviewed,³ and others will be reviewed at a later date.

The purpose of this paper is to give a single case report of a male baby, five months old, who had congenital cataracts and one hydrophthalmic eye; the other eye had a hypertension but was never hydrophthalmic. Goniotomy was performed four times on the hydrophthalmic eye and once on the other eye, as a result of which the tension was normalized, so that atropine could be used freely. Following these procedures each lens was needled once. A good red reflex in each eye resulted, and a careful study of the nonhydrophthalmic eyegrounds has been made; the disc is of normal color and outline, is not depressed, and there is normal physiologic cupping. Both eyes have been repeatedly studied gonioscopically by several members of the staff of the Illinois Eye and Ear Infirmary. The pupils are central and react to light, the corneas are clear, and the baby has enough vision without his glasses so that he can see and play with his toys. Although he is now 2 years and 4 months old, he does not walk and he is definitely slow in talking. The ears are slightly prominent and are proportionately large for the head.

CASE REPORT

Kenneth K. was first seen at the Illinois Eye and Ear Infirmary on May 23, 1942, when he was five months old. A diagnosis was made of R.E., cataract; L.E., hydrophthalmos and cataract. The mother first noted a clouding of the left eye when the baby was six weeks old. Gradually the left eye became larger than the right, and the clouding of the cornea remained. He was the only child, was not

born prematurely, and the delivery was spontaneous. The mother was ill for about six weeks during the first part of the pregnancy. There were no eye defects in any member of the mother's or father's families, nor tuberculosis, syphilis, diabetes, nor malignancy. There had been no infection in either eye.

Findings. The cornea of the right eye was 10 mm. in diameter; of the left eye 12.5 by 13 mm. The anterior chambers were of normal depth, the irides blue-gray, the pupils 2.5 mm. in diameter. The cornea of the right eye was clear; that of the left generally a little gray. There was a central opacity in each lens, and a red reflex was seen only on ophthalmoscopic examination. Nystagmus was present. The head was somewhat small (no measurements were taken), but there were no gross abnormalities of the head or body. Pilocarpine 1 percent was ordered for the left eye q.i.d.

May 26, 1942. With the child under ether anesthesia, no change was observable in the appearance of the eyes. Tension was R.E. 31 mm. Hg (Schiotz) (normal 12 to 24); L.E. 46 mm. Hg. Transillumination induced a good glow throughout.

Operation. The goniotomy knife was inserted at the limbus of the left eye at the 3-o'clock position, passed across the pupil to 9:30 o'clock, and swept down in the angle to 7 o'clock—that is, in the inferior nasal quadrant. Bichloride ointment and bandage were applied.

On the next day the cornea of the left eye appeared less cloudy. Pilocarpine 1 percent was ordered for each eye q.i.d. for two days and to be continued R.E. q.i.d.

The child was reentered on June 30, 1942, and discharged July 2d. Pilocarpine 2 percent was ordered R.E. t.i.d. R. and L. tension +1 (fingers).

L.E. Gonioscopy preceded the operation, performed under general anesthesia.

The cornea was still somewhat cloudy, precluding good visibility. Four of us agreed that there were two small areas at about the 7- and 9-o'clock positions together occupying possibly 25 degrees of arc, where the iris and its attachment to the sclera were pulled away and lay somewhat behind the plane of the rest of the iris; that is, there seemed to be a depression of the plane of the iris (internal cyclodialysis?). Elsewhere there were trabecular synechiae, and especially at the 2:30- and 3-o'clock positions; at the site of the original puncture there was a denser synechia.

Operation. Left eye: Again the knife was inserted at the 3-o'clock position and passed across to engage the trabecular region at 11 o'clock. A slight cut was made circumferentially to 2 o'clock—that is, in the upper quadrant. After withdrawal of the knife a slight amount of blood escaped into the anterior chamber. Bichloride ointment and bandage were applied.

Pilocarpine was continued in R.E.

July 16, 1942. Tension, R.E. was 19; L.E. 22 mm. Hg (local anesthesia).

The child reentered the hospital on September 15, 1942, and was discharged on September 19, 1942. Under ether anesthesia, tension R.E. was 30; L.E. 26 mm. Hg.

Operation. At this time goniotomy was performed on each eye, for it was evident that the medication used was not sufficient to control the tension of the right eye and the two previous operations were not sufficient for the left eye.

R.E. Entry was made at the 9-o'clock position; the needling knife was passed across to 2:30 and swept upward to 12 o'clock—that is, in the upper nasal quadrant.

L.E. Entry at 9 o'clock; the needling knife was passed across to 2:30 and swept downward to 5 o'clock—that is, in the lower temporal quadrant.

A few pinpoint spots of hemorrhage resulted along the root where the incision was made.

Pilocarpine was ordered, 1 percent R. and L., q.i.d. for two days postoperatively.

The child reentered the hospital on September 29, 1942, and was discharged on October 1st.

*Operation.** Under general anesthesia, goniotomy was performed on the left eye. Puncture was made at the 9:30-o'clock position, the incision extending upward from 3 o'clock to 12 o'clock—that is, the upper temporal quadrant. Very slight bleeding occurred at the 3-o'clock position. The patient was put on his right side. The anterior chamber re-formed in a few minutes.

On October 1, 1942, the tension L.E. was slightly soft (fingers).

Between October 20th and November 20th the tension O.U. was in the 20's, not increased with atropine.

The child reentered the hospital on December 8, 1942, and was discharged on December 11th. The right eye was needled under general anesthesia.

The child reentered the hospital on April 20, 1943. Under ether anesthesia the tension was R.E. 21; L.E. 22 mm. Hg. Atropine was instilled in each eye. The pupil of the right eye measured 3 mm.; that of the left 4 mm. The media of the right eye were clear, the disc was clearly seen. There was normal physiologic cupping; no atrophy. Retinoscopy, +16.00D. sph. at 0.5 meter.

Gonioscopy, R.E.—there was a good angle; the root of the iris was depressed in the area that had been operated on. L.E.—there was a good angle temporally especially from the 2:30- to the 3:30-o'clock position and nasally from 8:30 to

* Details of this preoperative examination were not found on the hospital record.

10 o'clock, with a depression of the root of the iris.

Operation. The left eye was operated on by needling horizontally with a Ziegler knife from the 9- to the 3-o'clock position. A good opening was obtained. Atropine was omitted.

Glasses were ordered as follows: O.U. +13.00D. sph.; add +4.00D. sph. ultex bifocals.

March 28, 1944. The nystagmus continued O.U. The patient did not like his glasses.

The corneas were clear; the pupils R. and L., 2 mm. in diameter. The tension was R.E. 23; L.E. 15 mm. Hg (butyn anesthesia).

The cornea of the right eye was 11+ mm. in diameter; that of the left 12+ mm. The patient has had no treatment for 11 months.

May 3, 1944. The patient was 2 years, 4 months old.

He had been quite ill following the last examination on March 28th, but recovered. He finds his toys and avoids objects; crawls with ease and rapidity. He stands, but not well; does not walk. The eyes do not tremble so much, especially toward evening. No redness of either eyes was observed. The muscles are all active, but he tends to look upward for the most part. The scleras are not especially blue.

The cornea of the right eye was 11+ mm.; of the left eye 12+ mm. in diameter.

The pupil of the right eye was 2 mm. and 1.5 mm. red reflex. The pupil was almost round and almost exactly central.

The pupil of the left eye was 2+ mm. and 1.5 mm. red reflex—almost round. The pupil was very slightly nasally placed.

Each anterior chamber was deep.

Under ether anesthesia photographs were taken. The tension was R.E. 20, L.E. 16 mm. Hg. The cornea of the right

eye was 11.25 mm., of the left eye 12.5 mm. in diameter.

Gonioscopy, L.E. only. The patient was examined by Drs. McGarry, Haas, Kronfeld, and Allen. At the 9-o'clock position a small area of ciliary body was seen between attenuated adhesions (anterior synechiae). At the 10-o'clock position there were four extensions of iris (McGarry) to the trabecular region. Just anterior to the ciliary body was a small area which may lead into the Schlemm canal. Between 4 and 5 o'clock there is a similar longer and deeper groove which seems to lead in to the sclera, posterior to Schlemm's canal.

SUMMARY

In brief review, we have here the case as a 5-month-old child with congenital glaucoma of low grade in one eye and early hydrophthalmos in the other; in each eye there was an associated cataract. The tension under narcosis was 31 and 46 reduced to 20 and 16 mm. Hg by one and four goniotomies, respectively; subsequently atropine, used previous to needling, did not raise the pressure. A single needling only was necessary in each eye. The result was a clear, centrally placed, round pupil in each instance, and a good view of each fundus was obtained. The vision without glasses is sufficient to allow the child to play with his toys; unfortunately it is too early as yet to estimate the acuity more accurately.

CONCLUSION

This method is not advocated as universally applicable in all cases of deep-chamber glaucoma, nor in all cases of hydrophthalmos; it is merely intended to record what has been accomplished in this one case. The operation is not more difficult but rather less difficult than a cataract extraction. When successful it preserves the symmetry of the pupil and

the normal appearance of the eye. Should it be unsuccessful, other operations of a similar or different character can be attempted. In my opinion goniotomy—in-

cision in the angle—should be added to the operative procedures at our command in the control of early glaucoma.

A CONTRIBUTION TO THE THEORY OF BINOCULAR VISION SUPPORTED BY THREE CASES OF LATENT NYSTAGMUS

ADOLPH POSNER, M.D.

New York

Latent nystagmus will be discussed in this article only insofar as it contributes to an understanding of the physiologic processes involved in binocular vision. The three cases reported herewith have been selected from a considerable number studied because they seemed best suited to illustrate the author's thesis. In order not to obscure the principal theme by a mass of unessential detail, it was deemed advisable to stress only the high points of the case histories.

THEORIES OF BINOCULAR VISION

The generally accepted views regarding the mechanism of binocular vision and stereopsis are based on Hering's theory¹ which may be briefly stated as follows: If the image of a given point in space were to fall on the fovea, it would seem that it ought to be projected back along the visual axis of that eye. However, in binocular vision this is not the case. Rather, the image is projected along the visual axis of a hypothetical cyclopic eye, or binoculus, which lies midway between the two eyes. Thus, no matter which one of the two foveas receives the image, the latter is projected in space

along the same line, which lies in the median plane of the head. Hence, the two foveas may be regarded as corresponding points. In general, any pair of points on the two retinas that are projected in space along the same line, are corresponding points. Disparate points, if the disparity is slight, help in the estimation of depth. In fact, Hering goes so far as to assign a definite depth value to any given pair of disparate points. The theory also assumes that the two eyes see simultaneously and that two independent visual sensations are registered in the cortex, these two sensations being combined somewhere in consciousness to form a single three-dimensional representation.

Verhoeff² has proposed a theory that differs materially from that of Hering. At any given moment the visual field contains some objects that are seen binocularly and others that are seen with one eye only. Yet it is impossible to detect where binocular vision ends and monocular vision begins. Hence, binocular vision cannot belong to a category different from monocular vision. Starting from this concept, Verhoeff has elaborated his

theory of "replacement," according to which the two eyes do not see simultaneously, but only one at a time. One eye will see certain portions of the whole field or of any single object, while the other eye sees the remaining portions. As in the case of binocular retinal rivalry, the portions seen by each eye are subject to momentary fluctuations, depending on the relative attention-values of the part-fields belonging to each of the two eyes. At any given moment, while one eye is occupied with the observation of one portion of space, the other eye is suppressed in this region, and in this region only. Thus the two eyes divide between each other the entire field of vision in an ever-changing mosaic of small monocular part-fields.

Verhoeff's theory carries a further implication that is of interest in this connection. When a configuration is seen binocularly, each monocular image is displaced in space to a new position corresponding to the binocular projection. This new position of a given monocular image is maintained even if a portion of the partner image is invisible. Stated in other words, even though both eyes collaborate in binocular vision, each eye retains a certain degree of independence and is able to supplant portions of the binocular field not seen by the other eye. Thus the configuration appears as an unbroken whole, the parts seen with both eyes being indistinguishable from those seen with one eye only.

This concept of the mechanism of bin-

ocular vision seems to be in accord with clinical observations. It explains, better than Hering's theory, most of the phenomena of binocular vision. However, the evidence that thus far has been brought forward in support of Verhoeff's theory was arrived at largely by introspective methods. For it is impossible to determine, by purely objective tests, which eye is fixating at any given moment; nor is it possible to detect in a normal individual to what extent the binocular field of vision replaces the monocular fields.

Observations made on patients with strabismus associated with false projection and marked amblyopia have led the present writer to conclude that good central vision is not essential to make binocular vision possible. By employing the "performance test"* of Davidson³ it may be demonstrated that most persons with amblyopia and central suppression possess at least a crude degree of binocular depth perception, since the latter becomes markedly impaired when the amblyopic eye is covered. In fact, it has seemed to the author that the overlapping of the two peripheral fields alone is sufficient to establish a certain amount of binocular depth perception. These observations, though highly suggestive, again suffer from the weaknesses inherent in subjective studies.

While engaged in this study, the writer noted that when latent nystagmus was associated with the monocular amblyopia, the effect of the amblyopic eye upon the good eye could be observed not only

*The technique of Davidson's "performance test" is as follows:

The patient is given a 4-mm. test object which he holds vertically in front of him at a distance of 50 cm. He moves this test object downward to touch a similar test object held by the examiner at approximately the same distance from the patient. By varying slightly the position of his test object with each trial, the examiner eliminates the patient's muscle sense as a factor.

Davidson claims that binocular depth perception, as shown by this test, should be lost in the field of suppression. Yet, he admits that the 4-mm. test object provides for a visual acuity as low as 20/600. Whatever the theoretical consideration may be the fact remains that, in the author's experience, patients with monocular amblyopia and false projection show a marked facility to judge depth binocularly, as compared with monocular vision.

subjectively by the higher binocular visual acuity and depth perception as compared with the same functions in monocular vision, but the amblyopic eye also exerted an objectively observable steadying influence upon the nystagmic movements of the normal eye.

The three cases of latent nystagmus reported here will serve to illustrate the argument.

REPORT OF CASES

Two of the cases, being very much alike, will be considered together. Both patients were girls in their early teens. Both had insignificant refractive errors, amblyopia of the right eye, and convergent strabismus. On covering the amblyopic right eye, a very pronounced conjoint horizontal nystagmus with a slight rotatory component was produced, the rapid phase being to the left, or away from the covered eye. In both cases the vision was 20/20 with both eyes open. On covering the amblyopic eye, however, the vision of the good eye dropped to 20/40 and 20/50, respectively. Thus the amblyopic eye, although itself having a very low visual acuity (15/200 and hand movements, respectively), and false projection, was, nevertheless, able to inhibit the nystagmus and to raise the visual acuity of the good eye by at least 100 percent. This inhibitory action was not affected either by placing a +10D. lens in front of the amblyopic eye or by interposing a disc 10 mm. in diameter so as to eliminate central vision.

The third case, that of a young woman aged 21 years, differed from the others only in that it exhibited a high refractive error and a divergent strabismus of the amblyopic right eye. Her refractive error and visual acuity were as follows:

Findings under cycloplegia: R.E. -14.00D. sph. \approx -4.00D. cyl. ax. 35°; L.E. -7.00D. sph. \approx -3.00D. cyl. ax.

175°. Corrected visual acuity: R.E. Counts fingers at one foot; L.E. 20/40+2; Both eyes, 20/20.

Even with both eyes open, a fine horizontal nystagmus to the left was occasionally observed. This became greatly exaggerated on covering the right eye. The afterimage test disclosed false projection in the right eye. As in the other instances, the nystagmus was not aggravated, nor was the visual acuity of the left eye lowered, by interposing a 10-mm. disc between the amblyopic eye and the fixation object.

Comment. In all these cases, the amblyopic eye, though itself possessed of a very low visual acuity, exerted a steadying influence on the other eye. This influence is probably a function of the peripheral retina, since it was not abolished by interposing a small opaque object between the amblyopic eye and the fixation point. Whereas in these cases only one eye was capable of central vision, the other supplying the steadying influence through its peripheral retina, in normal subjects these two functions are interchangeable and, in fact, do continually shift from eye to eye.

THE MECHANISM OF LATENT NYSTAGMUS

Since it is a known fact that fine nystagmoid movements are normal accompaniments of foveal fixation, latent nystagmus may be regarded as a quantitative, rather than a qualitative, deviation from the normal. It may thus represent a developmental defect of the motor phase of the sensorimotor mechanism involved in binocular vision.

The physiologic make-up of the central nervous system is such that the final common path is controlled by a series of functional levels. These levels are integrated among themselves in such a way that the higher levels of innervation exert an inhibitory influence on the lower

levels. The best-known example of the uninhibited action of the lower centers is the decerebrate state. Here one finds a redistribution of the tonus according to a definite pattern. Among other features, the movements of muscle groups are characteristically clonic in nature. One of the functions of the cerebral centers is to throw the impulses generated by the lower centers out of phase, so as to make possible a smoother action of the musculature.

The extraocular muscular apparatus, similarly, requires this cortical control in order to make possible a steady and continuous fixation, which is a prerequisite of good visual acuity. Binocular fixation brings the cortex into play to a higher degree than would be possible were either eye to be used alone. It thus appears plausible that binocular participation in the visual act plays a role in inhibiting the nystagmus in certain cases. This inhibitory action may be complete or only partial. In the latter case the nystagmus diminishes in amplitude while increasing in frequency. This may be owing to the fact that the impulses transmitted to the individual muscle fibers are thrown out of phase instead of being summated into coarse movements. In proportion to the reduction of the amplitude of the nystagmus one also notes an increase in the visual acuity. The curious fact noted in these cases of latent nystagmus is that the most rudimentary type of binocular vision and a truly insignificant degree of visual acuity in one of the eyes are sufficient to inhibit the nystagmus.

In a previous communication the

writer⁴ has called attention to an analogous, though reversed, situation which obtains in the noncomitant hyperphoria of amblyopic eyes. In these cases the visual and fixational processes of the good eye affect the position of the amblyopic eye. For instance, covering the good eye results in a downward movement of the amblyopic eye. In latent nystagmus, on the other hand, covering the amblyopic eye brings on, or increases, the nystagmus of the good eye.

OCULAR DOMINANCE EXPLAINED BY "REPLACEMENT" THEORY

The observations made in these and other similar cases when viewed in the light of Verhoeff's replacement theory, permit some deductions to be made with regard to the concept of ocular dominance.

While one eye fixates, the other eye supplies the spatial setting for this act. One may think of the fixating eye as analogous to the foreground action on a stage, while the other eye represents the general setting of the scene. In other words, one eye supplies foveal vision, while the other supplies the peripheral field. If both eyes are equivalent as regards visual acuity, these two functions are interchangeable, and the eyes assume alternately the role of fixation. But even so, one eye fixates for a greater proportion of the time than the other. This eye is the dominant eye. Since most of the conventional tests for dominance are sighting tests, their function is really to determine which eye prefers to fixate, or which eye sees the more real image when physiologic diplopia is induced.* Ocular

* A very simple test for dominance which, in the author's experience, has proved fully as reliable as the more elaborate procedures, consists in having the patient raise his finger and, with both eyes open, sight one of the examiner's eyes. If the examiner then shuts his other eye momentarily, he can tell immediately which of the patient's eyes is covered by the finger. This is the dominant eye.

The determination of the dominant eye has a certain practical value in a routine refraction.

dominance, thus, does not refer to the vision as a whole, but merely to the act of fixation, which constitutes the motor response to sensory stimuli. Regarded from this point of view, the relationship between eyedness and handedness can be more easily understood.

SUMMARY

1. Three cases of latent nystagmus with amblyopia of one eye are presented.

2. The nystagmus may be interpreted as a modification of normal fixation-

movements.

3. The nystagmus is inhibited by a minimal amount of binocular vision, which apparently brings into play a higher degree of cortical control than does monocular vision.

4. Observations made on these cases confirm the validity of Verhoeff's "replacement" theory of binocular vision.

5. The "replacement" theory also serves to explain the phenomenon of ocular dominance.

It is always advisable to guard against overcorrecting the nondominant eye, even if by so doing the visual acuity can be brought up slightly. The patient prefers to wear a correction which favors his dominant eye, so that a normal relationship between his eyes is maintained.

NOTES, CASES, INSTRUMENTS

AN AID IN USING THE PRISM COVER TEST IN THE CARDINAL DIRECTIONS OF GAZE

H. SAUL SUGAR, MAJOR (MC), A.U.S.
Vancouver, Washington

The prism cover test has become generally accepted in most clinics in the United States for measuring ocular deviations in the various directions of gaze in patients with normal fixation with each eye. There has been, however, little or no attempt to standardize the actual angle of deviation of gaze at which these measurements should be determined. Especially in comparing the angle of deviation before and after surgical treatment of ocular-muscle pareses is it important that the measurements be made at the same position of gaze.

One of the commonest methods used to determine the deviation in the various directions of gaze is to have the patient tip his head obliquely while fixating a distant or near point. This is not only a crude measurement but, as Adler¹ has pointed out, is erroneous in that one

source of muscle tone, that due to the fusional impulses from the labyrinth and neck, is removed. The measurements should therefore be made with the subject's head erect and the eyes turned in the desired direction of gaze. Two questions then arise, first the angle of

Fig. 2 (Sugar). Frame in place. Arrows point to 20-degree markers. Numerals 1 and 2 indicate the centers for each eye.

Fig. 1 (Sugar). Frame used to measure 20-degree angle of deviation of gaze. Arrows point to 20-degree markers. Numerals 1 and 2 indicate the centers for each eye.

deviation of gaze at which the measurements should be made, and, second, the actual method of measurement. The first question has been answered by Friedenwald² and, in my experience, is correct. Friedenwald's tests in a study of anisophoria indicated that 20 degrees off axis is the maximum deviation which it is convenient to use. This represents the limit of the field of ocular rotation ordinarily used in moving the eyes without moving the head. Beyond 20 degrees the fixation may become unsteady. Friedenwald also points out that 20 degrees is roughly the angular difference in position of the eyes for vision at distance and for reading.

The apparatus shown* in figures 1 and 2 was devised as a simple means of indicating the 20-degree angle in the cardinal directions of gaze. It is made of 0.045-inch piano wire soldered to a spectacle frame. A leather strap is attached so that the centers can be adjusted to the level of the pupils. This apparatus is very light in weight and permits the examiner to place prisms before one eye with one hand and alternately to cover the eyes with an occluder held in the other hand. The distance from the spectacle frame to the measuring points is 8 inches, a convenient, arbitrary distance chosen so that the apparatus would not be too bulky but yet permit the examiner to insert his hands through the openings at the

sides. The diameter of the rim attached to the spectacle frame is 16 inches. The distance between the two centers is 62 mm., taken as the average interpupillary distance for near.

In using the apparatus, the angle is measured from the center point on the side of the abducted eye. The device may be used for either distance or near fixation, although I regularly measure the deviation in the cardinal directions of gaze for near only. The patient is asked to look past the 20-degree marker on the frame at the point of fixation while the examiner inserts the prisms and occluder to perform the cover test. The examiner keeps the fixation point in line with the marker and the visual line of the abducted eye during the performance of the test.

OPHTHALMOLOGY IN BRAZIL*

M. A. DA SILVA, M.D.

São Paulo, Brazil

Brazil has 11 medical schools, each one of which teaches undergraduate ophthalmology. In each Department of Ophthalmology there are a professor, several associate professors, and several assistant instructors. No reference will be made here to the general medical curriculum. The lectures of ophthalmology for undergraduate students are given in either the fifth or the sixth year, the course varying from 6 to 12 months. Three lectures a week of one hour each followed by two hours of practical work are given, and at the termination of the course an oral,

written, and practical examination is made. The amount of material covered varies from a complete course in ophthalmology to various lectures pertaining to the diseases of the eye as related to general medicine. The main purpose of this undergraduate course is to prepare the student to recognize and treat the common diseases of the eye and understand the intimate relationship between ocular disease and general systemic disturbances.

There is generally close collaboration between the Department of Ophthalmology and the Department of General Medicine, so that consultation may be obtained when desired.

Postgraduate internship in ophthalmology is available in the various medical schools, and the usual period of service

* Because of transportation difficulties no corrected proof from the author was obtained.

varies from one to two years. If for any reason the student cannot carry out such a program of one to two years' additional study after graduation, he may, if he chooses, during his last one to two years of medical-school work, take additional instruction in ophthalmology in conjunction with his medical training, so that upon graduation he may be able to practice this specialty.

In addition, various special courses in ophthalmology are given every year in São Paulo and in Rio de Janeiro, available to ophthalmologists and general physicians who wish to become ophthalmologists. In São Paulo these courses have been regularly held by the Escola Paulista de Medicina and occasionally by the Faculdade de Medicina. They last one month and are intensive. The course is divided into two parts—the first part for beginners in the essential elements of ophthalmology and the second, more advanced, part for those who are practicing the specialty. The latter deals with the modern trends in ophthalmology. Various courses in any branch of ophthalmology are available the year round in São Paulo at the Escola Paulista de Medicina.

There are approximately 600 ophthalmologists in Brazil, but they are unequally distributed throughout the country. The greater number are located in Rio de Janeiro, São Paulo, Porto Alegre, Bello Horizonte, Bahia, and Recife. The ophthalmologists in the interior are not limited usually to ophthalmology but practice otorhinolaryngology as well. The main centers of ophthalmology in Brazil are at São Paulo, Rio de Janeiro, Porto Alegre, Bello Horizonte, and Bahia. Among the tropical diseases that are more frequently observed are cysticercosis, myiasis, blastomycosis, and other parasitoses. Cysticerci have been more frequently observed in the vitreous in the subretinal space, whereas myiasis are

observed in the lids and conjunctiva. In the cases of intraocular and external diseases due consideration is generally given to intestinal parasitoses, an etiologic factor. The other ocular diseases are observed more or less frequently. Their etiology is syphilis, focal infections, and tuberculosis, the treatment for which follows the well-accepted therapeutic methods.

Regarding ocular surgery, various procedures are employed, depending on the individual surgeon. When surgery is indicated for the lacrimal ducts the common procedure is dacryocystectomy and very rarely dacryocystorhinostomy. The underlying reason for this procedure may be explained on the following basis: In the latitude where we live, there is practically no winter. The temperature is even at all times. The average minimum is about 56°F. and occurs in June. Epiphora is practically minimal. In cataract surgery the conjunctival suture is the favorite. Extracapsular extraction is far more frequently used than intracapsular. As to whether the section is done with the Graefe knife or keratome depends on the choice of the surgeon. In glaucoma surgery iridencleisis is rarely practiced.

Refractions are done exclusively by ophthalmologists. We do not have optometrists in our country, for the law does not permit the optometrist to prescribe glasses and does not permit any relationship between the ophthalmologist and the optician for dispensing the glasses.

Among the ocular infections the most common are trachoma and ophthalmia neonatorum. Trachoma constitutes a sanitary problem. It is more prevalent among the people that have immigrated from Spain, Portugal, Italy, and Syria, and is more or less endemic. The type of trachoma prevalent is relatively benign, very rarely resulting in blindness if treated correctly. Ophthalmia neon-

torum is, unfortunately, found relatively frequently in spite of the mandatory use of the Credé method. Acute catarrhal conjunctivitis is an epidemic in certain regions where it is often confused with trachoma. We have not observed epidemic keratoconjunctivitis in Brazil.

Modern equipment is used in the principal clinics and offices.

An intense campaign by the ophthalmologists and ophthalmologic societies of Brazil has been instituted for the prevention of blindness. The principal causes of blindness are trachoma, ophthalmia neonatorum, syphilis, and glaucoma. A social center for the prevention and treatment of glaucoma and infectious diseases is functioning at the Department of Ophthalmology of the Escola Paulista de Medicina, in São Paulo. The National Society for the Prevention of Blindness in Brazil, also has regional offices which constantly carry on a rigid campaign with the foregoing aims in mind. Brazil has several schools for the blind where they learn various occupations and at the same time read the classic Braille. There are also schools for the amblyopic.

All the Brazilian ophthalmologists are members of the ophthalmologic societies. There are eight ophthalmologic societies in Brazil, one in each of the following cities: Rio de Janeiro (Sociedade Brasileira de Ophthalmologia), São Paulo (Centro de Estudos de Ophthalmologia and Sociedade de Ophthalmologia de São Paulo), Campinas, São Paulo State (Associacao Medica do Instituto Penido Burnier), Porto Alegre (Sociedade Riograndense de Ophthalmologia), Bahia (Sociedade Bahiana de Ophthalmologia), Recife (Sociedade Pernambucana de Ophthalmologia), and Belem (Sociedade Paraense de Ophthalmologia). All the societies meet regularly for the presentation and discussion of papers; these are published in special

journals. The official organ of the Pan American Congress of Ophthalmology is published in São Paulo (Ophthalmologia Ibero Americana). The Brazilian Congress of Ophthalmology and Argentine Congress meet every two years. Three outstanding reports on previously chosen subjects are presented by Latin American ophthalmologists at these meetings. When the meeting is held in Brazil, two of the scientific papers are presented by Brazilian ophthalmologists and one by an Argentine. When the Congress is held in the Argentine, the process is reversed. The coöperation between the two countries is excellent.

At the last Brazilian Congress of Ophthalmology, which was held in Rio de Janeiro in 1941, Dr. Harry S. Gradle of Chicago rendered an outstanding service to Brazilian ophthalmology by supporting our project of establishing a Brazilian Board of Ophthalmology. This, we hope, will raise the standard of our specialty as the American Board has done in the United States. For his most generous aid, all our men in this field express their deepest gratitude.

CHRONIC CONJUNCTIVITIS CAUSED BY CYSTOID DE- GENERATION OF THE UPPER CANALICULUS*

VERNON M. LEECH, M.D.
Chicago

In cases of chronic conjunctivitis that resist treatment, the usual procedure is to test the drainage apparatus, either by instilling a colored solution into the conjunctival sac and trying to recover it from the nasal secretions, or by syringing the lacrimal sac through the lower canalicu-

* Read before the Chicago Ophthalmological Society, May 15, 1944.

lus. If the sac is found to be patent, local lid therapy is resumed in the hope of eventually obtaining a cure. If an obstruction is found, recourse is had to surgical treatment. Usually the upper canaliculus is ignored and because of this omission the cause of the trouble in the case to be reported was not found as early as it might otherwise have been. The patient had been treated by two reputable ophthalmologists and members of a well-known clinic in this city, but without eliciting the etiology. After each session of treatments, the conjunctivitis materially improved and the patient was discharged as cured or, as in one instance, she gave up after six months because of the long-drawn-out course of treatments. The distinct advantage in being the fourth ophthalmologist to see the case is obvious.

The literature is unanimous in stating that obstruction of the canaliculi is caused by fungus infection.

Duke-Elder under the heading of "Lacrymal conjunctivitis," gave the best textbook description of this condition as follows:

This term is sometimes applied to a chronic conjunctivitis caused by obstruction and infection of the lacrymal passages. The organisms therefrom, usually streptococci or pneumococci, continually infect the conjunctival sac, keeping up the symptoms of a chronic inflammation of the mucous membrane and the lid margins. . . . The condition is worthy of note from the clinical point of view in that its cause—a streptothrix in the canaliculus, for example—is frequently missed, with the result that a chronic conjunctivitis goes on indefinitely in spite of treatment. . . .

In adding case reports to the literature many authors, one after the other, stated that the condition is rather uncommon; but if one sums them up the total is rather formidable for so rare a condition. One is impressed, in checking over the available literature for the past 40 years, by the paucity of data on this subject prior to

1921, but between that time and 1940, 21 cases were reported. Undoubtedly others have occurred that have not been recorded.

The most comprehensive report on the subject was made by Elliott* who presented data on nine cases that were seen at the New York Eye and Ear Infirmary in two years. Streptothricosis was given as the cause of all of them. He divided his cases into two groups: (1) those with canalicular signs predominating, and (2) those with marked conjunctival reactions without apparent canalicular signs. Duration of symptoms was one month to three years. Five of his patients had lower-canalculus involvement, 2 had upper-canalculus involvement, and 2 had infection in both; 4 had very slight swelling around the punctum, 2 had marked swelling around the punctum, and 3 had no external signs.

CASE REPORT

Miss B. M., aged 48 years, presented herself a few weeks ago complaining of almost constant "infection" of the right eye for the past 18 months, during which time she had been treated by two ophthalmologists, also at a recognized eye clinic. Under treatment, the eye became almost well but she noticed a little pus in the corner every day even when it was at its best. When treatment was stopped, the eye soon became inflamed again.

Examination. Visual acuity right eye, 20/20+; left eye, 20/25+. The lids of the right eye were brawny in appearance and slightly edematous. Considerable pus secretion was present in the conjunctival sac; the conjunctiva of the lids and fornices was very red and thickened; the bulbar conjunctiva was only slightly injected. Cultures and smears were reported

* Elliott, A. J. Streptothricosis of lacrimal canaliculi: 9 cases. *Amer. Jour. Ophth.*, 1941, v. 24, June, pp. 682-686.

to contain *Staphylococcus albus* and pure diphtheroids. The left eye appeared normal in all respects.

Treatment. Silver nitrate 2 percent was applied to the conjunctiva every second day. The patient was given argyrol 20 percent to be instilled in the eye three times a day and zinc sulfathiazol ointment 5 percent to be put into the eye at

Fig. 1 (Leech). X-ray picture showing boundaries of cyst in case of degeneration of the upper canaliculus.

bedtime. At the end of a week the eye was much improved. Office applications were changed to zinc sulphate solution 2 percent every second day for the next 12 days. At the end of this period the conjunctiva was almost normal in appearance, but a little pus was still present in the inner canthus every day. The tear sac was therefore investigated by syringing through the lower canaliculus. To my surprise the fluid passed freely into the nose and no pus whatever was returned. At the patient's next visit, upon everting the upper lid, I observed a tiny bead of pus exuding from the upper punctum, which gave the cue to investigate the upper canaliculus. After the punctum was dilated a lacrimal needle was inserted. Instead of meeting the usual resistance from a normal canaliculus, the needle could be moved around in all directions under the skin. With the needle as a probe, a flat cavity, measuring approximately 5 mm. vertically by 7 mm. horizontally and collapsed antero-posteriorly,

was made out. No pathologic changes could be found on palpation. When fluid was forced through, considerable pus flowed back along the needle but no fluid entered the lacrimal sac. Iodized oil was then instilled to mark the boundaries of the cyst and X-ray pictures were taken.

Later a small cataract knife was inserted through the upper punctum into the cavity and the lid was incised as is done in slitting a canaliculus. Two typical greenish, waxlike concretions, one 2 mm. in diameter and the other slightly smaller, were removed with a curette along with some pus and other debris. The lining of the sac was cauterized with trichloroacetic acid, and the eye bandaged for 24 hours. Healing was uneventful, and within one week there was no accumulation of pus in the conjunctival sac. The patient was comfortable and happy.

DEDUCTIONS FROM THE LITERATURE AND FROM MY CASE REPORT

1. Fungus infection and obstruction of the canaliculi would seem to be common enough to cause embarrassment to the ophthalmologists who find that they have missed the diagnosis. Many patients have suffered from annoying conjunctivitis for months, even years, before diagnosis was made (one patient suffered eight years).
2. Chronic intractable conjunctivitis is the dominant symptom of a blocked canaliculus.
3. The condition is usually unilateral but the possibility of both eyes being involved should not be overlooked.
4. It is more common in women than in men.
5. External diagnostic signs, such as swelling over the canaliculus, turgescence of the papilla, or marked epiphora, may not be present.
6. Routine bacteriologic examination may not help in the diagnosis of cases of long standing.

7. In some instances fluid from a syringe can be passed through the involved canaliculus to the nose. In such cases diagnosis is more difficult unless pus is carefully watched for in the return flow.

8. Upper-canaliculus involvement is easier to overlook than lower, for the patency of the drainage apparatus is usually tested by syringing through the lower canaliculus.

TRIAL FRAME FOR YOUNG CHILDREN

WALTER H. FINK, M.D.

Minneapolis, Minnesota

The problem of refracting the very young child is made more difficult by the lack of an adequate frame. The adult trial frame may be used for children who are three years of age and older, but it is entirely inadequate for the child who is less than three years of age. Because we are frequently called upon to refract these younger children, and in some instances they are as young as one year, it is evident that a frame to satisfy this need should be available. A survey of the trial frames in present-day use reveals the fact that there is nothing that may be considered satisfactory.

To meet the need, a frame has been designed, molded from plastic material. The bows are straight and the nose piece is built so that the frame will not touch the lashes. There are no sharp edges that might cut the tissues. The interpupillary distance is 55 mm., which may be considered the average for a two-year-old child. A +3.50D. sphere with a metal rim is inserted into a channel in the plastic material and is so constructed that it can be removed readily if desired. This strength of sphere is used because

many children of this age have a lens requirement of 2.50D. of hyperopia. The additional 1.00D. is added so that the retinoscopic test can be done at a distance of 1 meter, thus eliminating the necessity of adding a compensatory sphere.

Two clips are placed before each lens so that a cylinder may be inserted in one

Fig. 1

and a sphere (plus or minus) or an occluder may be added to the other.

The frame can be used on an apprehensive child by whom another frame might not be tolerated. Because of its light weight, good balance, and no points of pressure, it is not annoying to the child. It can be applied and removed easily. The time necessary for the test is greatly reduced, which is an advantage in dealing with a young child. This reduction in time is made possible by the +3.50D. lens that is in the frame, because the examiners can frequently at a glance estimate the lens requirement; or, if this is not possible, the number of lens changes is greatly reduced.

Before applying the frame, the child's attention is concentrated on a mechanical toy held by the examiner. While thus occupied, the examiner slips the frame on the child and quickly estimates the correction by retinoscopy. The frame can be quickly removed and a lens added which will correct the astigmatism, or increase or decrease the spherical correction as the case may be. The process can be repeated several times in a few moments. Fre-

quently the child is not conscious of what is going on, he is so intent on watching the mechanical toy.

The writer has used the frame for over 10 years and has found it invaluable.

REFRACTION CLINIC*

DISCUSSION BY ALBERT E. SLOANE, M.D.[†]
Boston

A shoe worker, aged 52 years, noted during the past month that he had some mild vertigo which was exaggerated when reading or working at his machine. Believing this to be related to his eyes, since he had not changed his glasses for over five years, he went to an eye doctor. This person explained his symptoms on a basis

X = O.D., O = O.S. Plotted in arc degrees.

of need for bifocals, which he subsequently prescribed. The bifocals produced more symptoms, much more severe than he had had before the glasses were worn. He was labeled as a neurotic and was told it was simply a matter of "getting used to double-vision glasses."

EXAMINATION

His vision was O.U. 20/40, correctable

* From the House Officers' Teaching Clinic, Massachusetts Eye and Ear Infirmary.

[†] Director of Department of Refraction.

to 20/20, each eye, with: R.E. +1.25D. sph. \approx -0.25D. cyl. ax. 90°; L.E. +1.25D. sph; add +2.00D. sph. Wells #1 Type.

The patient had a 3^Δ esophoria and a 3^Δ right hyperphoria in the primary position. His old glasses measured: First pair (obtained over five years ago) +2.00D. sph., O.U., in single-vision lenses. The recent pair of bifocals measured +1.25D. sph., O.U., with +2.00D. sph. add. He volunteered that he could see better at near with his bifocals than with his old reading glasses, but was most uncomfortable and would become confused. In view of the sizable amount of hyperphoria a diplopia field was executed, and this revealed a paresis of the right superior oblique muscle. The quantitative diplopia readings in the depressor field varied from 12^Δ (6 arc degrees) to 4^Δ (2 arc degrees) right hyperphoria.

DISCUSSION

Obviously this patient's difficulties cannot be explained on a basis of his refractive error, *per se*. However, it is easy to explain the symptoms on a basis of his anisophoria. Since the heterotropia is within such small limits in straight-ahead and elevated fields, he has not been troubled by frank diplopia and probably kept his head sufficiently cocked so as to utilize his depressor fields (which were the highest handicapped) at a minimum. When bifocals were prescribed for him he had to use his depressor muscles in order to look through the segments, and since his depressor field had the most diplopia, the result was increased discomfort.

SOLUTION

In such cases where diplopia is not particularly disturbing, it is frequently not necessary to occlude one eye. The patient,

however, is allowed to compensate for his diplopia by tilting his head so that the eyes will be in a more advantageous position. Thus any optical correction for focusing the eyes should not be of such a nature as to hinder the person from holding his head and the direction of his eyes as serves him best. In this case bifocals are absolutely contraindicated and the patient is best served through prescribing single-vision glasses for distance and near. It so happened that this patient had a positive blood test and his paresis was explained on this basis.

QUESTIONS

House Officer: Could bifocals have been made with the reading segment above?

Dr. Sloane: In this case such a bifocal might have been acceptable since the reading portion would be located in the field of elevation where the diplopia was not a factor. However, as a general rule, bifocals are not satisfactory in cases of paresis of an extraocular muscle because there is frequent need for tipping the head to one side, which makes the person look through a different portion of each segment.

H.O.: What prompted you to execute a diplopia field in the absence of history of double vision?

Dr. Sloane: Any case in which there is a sizable amount of hyperphoria requires additional tests to classify the nature of the hyperphoria.

H.O.: What are these additional tests for classifying hyperphoria?

Dr. Sloane: First, a diplopia field to determine the presence of a paresis or overaction of a vertical muscle. Second, repeating the test with the fusion deceiving device (Maddox rod) before either eye to rule out the presence of an alternating hypertropia.

243 Charles Street (14).

CHART FOR RECORDING LOCATION OF CORNEAL INJURIES AND LESIONS*

FRANK H. RODIN, M.D.

San Francisco

The necessity for a chart showing the exact location of injuries and lesions to the cornea is obvious. We have been unable to find one in the ophthalmologic literature. Such a chart is especially desirable in view of the tremendous growth of industry in recent years with a corresponding increase in ocular injuries. The commonest of these is trauma produced by a foreign body imbedded in the cornea. Foreign bodies are removed not only by ophthalmologists but by industrial surgeons, general practitioners, and, at times, by a nurse at a first-aid station. In the majority of cases, the record supplied fails to specify the precise location of the injury. This is of great importance, particularly when a claim is later made for loss of vision due to an injury to the cornea and examination shows more than one scar. A simple chart is also advisable to record quickly and accurately any corneal lesion that may present itself for treatment, such as a corneal ulcer. The progress of the condition, whether advancing or healing, can be accurately set forth on such a chart.

A simple chart for permanent recording of the exact location of corneal injuries and lesions is described. According to Fuchs,¹ the horizontal diameter of the cornea is 12 mm., and the vertical 11 mm. This chart (fig. 1) consists of five equidistant concentric circles and an ellipse. The distance between the circles represents 1 mm. The distance between the fifth circle and the periphery of the chart, the ellipse, represents 1 mm. in the

* From the Department of Ophthalmology, Mount Zion Hospital, San Francisco. This research was aided by a grant from the Columbia Foundation.

horizontal direction and 0.5 mm. in the vertical direction. Thus, in the horizontal direction there are six arcs on either side of the center, each representing 1 mm. distance from center to perimeter. In the

position. For example (fig. 2), A would indicate a foreign body 1 mm. in size, 2 mm. from the center in the direction of the 2-o'clock position. B would indicate a corneal abrasion 2.5 mm. long, starting

Figs. 1 and 2 (Rodin). Corneal chart.

Fig. 1. Chart for recording location of corneal lesions; it consists of five equidistant concentric circles and an ellipse. The distance between the circles represents 1 mm. The distance between the fifth circle and the periphery of the chart, the ellipse, represents 1 mm. in the horizontal direction and 0.5 mm. in the vertical direction. Thus, in the horizontal direction there are six arcs on either side of the center, each representing 1 mm. distance from center to periphery. In the vertical direction, the first 5 arcs represent 1 mm. distance from center to fifth arc, and 0.5 mm. from fifth to sixth arc. Twelve straight lines radiate from center to periphery of the chart 15 degrees apart, resembling the face of a clock.

Fig. 2. Method of marking corneal lesions on chart. The site is defined in terms of distance either from the center of the cornea or from the limbus, and the time o'clock position. For example, A would indicate a foreign body 1 mm. in size, 2 mm. from the center in the direction of the 2-o'clock position. B would indicate a corneal abrasion 2.5 mm. long, starting at 0.5 mm. from the limbus between the 3- and 4-o'clock positions. C would indicate a corneal ulcer at the limbus between the 7- and 8-o'clock positions, and extending for 2 mm.

vertical direction, the first 5 arcs represent 1 mm. distance from center to fifth arc, and 0.5 mm. from fifth to sixth arc. Twelve straight lines radiate from center to periphery of the chart, 15 degrees apart, resembling the face of a clock.

The classical landmarks are the center of the cornea and the limbus. The central point on the chart represents the center of the cornea, and the periphery represents the limbus. In describing a corneal lesion, the site is defined in terms of distance either from the center of the cornea or from the limbus, and the time o'clock

at 0.5 mm. from the limbus between the 3- and 4-o'clock positions. C would indicate a corneal ulcer at the limbus between the 7- and 8-o'clock positions, extending for 2 mm.

I use a rubber stamp made from an engraved wood cut 24 by 23 mm. in diameter, which is actually twice the size of the cornea. The patient's record is stamped, and a sketch of the corneal lesion is drawn on the chart. This is a permanent record, which can easily be translated in descriptive terms for a report.

MOTILITY CLINIC*

SUDDEN ONSET OF CONCOMITANT

CONVERGENT STRABISMUS

HERMANN M. BURIAN, M.D.

Hanover, New Hampshire

D. E. S., a boy aged 15 years, had a convergent strabismus of the right eye.

The history given was as follows: No case of strabismus, amblyopia, nor high refractive error was known to have occurred on either the paternal or maternal side of the patient's family. Aside from frequent colds and measles in early childhood, the patient had never been ill. One morning, three years ago, the mother suddenly noticed that the patient's right eye was turned in and the patient himself noticed diplopia. The eye straightened out in the course of the day, but it was again turned in the next morning and has remained in convergent position ever since. No fever, malaise, nor any disease preceded the turning of the eye. The left eye never turned unless the patient made a conscious effort to use the right one. The patient has permanent spontaneous diplopia which was at first most disturbing; he has now become adjusted to it. He was given glasses after the onset of the strabismus but they were discarded a year and a half ago with the consent of the patient's physician, since they had in no way influenced the strabismus or the diplopia.

The patient's report arouses the suspicion that he sustained a paralysis of the right external rectus muscle and that the convergent strabismus which he now displays is a sequel to this paralysis.

DIAGNOSIS

Uncorrected visual acuity was

20/15—2 in either eye. Refraction: R.E. +1.25D. sph. = 20/15. L.E. +1.25D. sph. \oslash —.25D. cyl. ax. 180° = 20/15.

Rotations. In levoversion there was a marked excess of adduction of the right eye; the abduction of the left eye was normal. In dextroversion there was an excessive adduction of the left eye, about as pronounced as in the right eye, but the *abduction of the right eye was normal*. The assumption that in this case the strabismus was of parietic origin is thus not borne out. The referring doctor who has followed the patient since the very onset of the strabismus also stated that he had never been able to discover a deficiency of abduction of either eye. The rotations up, down, up and right, and down and right were normal, but a slight lagging of the right eye was noticeable when the patient looked up and left and an excessive movement of that eye when he looked down and left. There was, in other words, a slight weakness of the right inferior oblique, accompanied by an overaction of the right superior oblique.

Cover test. The patient fixated with the left eye, but when that eye was covered he was able to assume and keep up fixation with the right eye. He could also voluntarily switch fixation from one eye to the other. The angle of squint appeared to be the same, whether he fixated with the right or left eye. Aside from the horizontal movement no other movements were seen in the cover test. The horizontal movement of the eyes was offset with prisms of 30^A, base out, in front of each eye. The movement stopped for both eyes with the same prism strength; in other words, the primary and secondary angles of squint were equal.

Double-image test. The patient had permanent spontaneous diplopia and the relative localization of the two spontaneously seen images had first to be investigated. The patient reported that he saw

* From the Clinical Division of the Dartmouth Eye Institute, Dartmouth Medical School. The cases described were demonstrated at a Staff Meeting of the Dartmouth Eye Institute.

the fixation light of the tangent screen double; one image was in the center, the other image to the right, a considerable distance from the central light, even beyond the screen. When the right eye was covered, the image to the right disappeared: the patient had an uncrossed diplopia. A dark-red filter was placed in front of his right eye. The left eye fixated the center light and the patient saw the red light to the right at a distance of about 30 arc degrees from the fixation light. The red filter was then placed in front of the left eye. The right eye fixated and the red light appeared to the left, again at about 30 arc degrees from the center. Since the second image was beyond the screen the distance of the two images could be determined only approximately. When the patient's angle of squint was reduced by one half by placing prisms of 15^{Δ} base out in front of each eye a distance of 15 arc degrees between the two images was found. There was no vertical deviation of the double images. The patient, then, showed *normal retinal correspondence in the double-image test*.

Prisms of 30^{Δ} , base out, were placed in front of each eye, thus compensating the entire angle of squint. The patient no longer saw the fixation light double; and when the red filter was now put in front of either eye, the red and white lights coincided.

Afterimage test. The patient first fixated for 10 seconds the center of the glowing filament of the tubular bulb while it was in the horizontal position, keeping the right eye covered. Then he covered the left eye and with the right eye fixated for 10 seconds the center of the filament, which was now in the vertical position. The room was darkened and the patient reported immediately that the afterimages of the filament formed a cross. The same was true of the negative afterimages which he saw in the lighted room: in spite

of the convergent position of the eyes the afterimages formed a cross. The patient presented *normal retinal correspondence* in the afterimage test and the speed and definiteness with which he reported the position of the afterimages demonstrated that there was no suppression.

Examination for binocular vision. It was of importance for the therapy to examine in this case the coöperation of the two eyes. Surgical procedure would seem to be the only means by which the condition could be corrected. But there was the danger that the patient might have *horror fusionis* and that the diplopia would persist after the eyes were straightened. It would then be much more disturbing than before surgery, because the double images would be close together.

It was unlikely that this patient had *horror fusionis*. The patient saw single when the angle of squint was compensated by prisms. This never occurs in cases of *horror fusionis*. Examination with the synoptophore confirmed the impression that the patient had no *horror fusionis* but a rather highly developed binocular coöperation. The following condition was found: The objective angle of squint, as measured with first-degree targets, was 62^{Δ} . There was a varying, small right hyperphoria of 0 to 1^{Δ} . Subjectively the patient superimposed the first-degree targets at 62^{Δ} of convergence. The same angle was found with second-degree targets, and there were fusional amplitudes of from 20^{Δ} of convergence to 4^{Δ} of divergence. The third-degree targets were easily fused at the objective angle, but it was doubtful whether the patient had stereopsis; in any case it was only rudimentary.

THERAPY

The question of therapy arises. The strabismus is disfiguring and the diplopia disturbing; the patient is eager to have

both handicaps removed.

Based on the results of the examination surgery is advocated. The patient stands an excellent chance for a good cosmetic and functional result.

The type of operation to be performed is determined by the rationale of operations on the extrinsic muscles of the eyes: they can change only the mechanical conditions; the choice of operation depends on the mechanical anomalies present in the case. The patient has a marked excess of adduction in both eyes; the abduction is normal. The action of the internal rectus muscles must, therefore, be weakened. A recession of the right internal rectus should be performed; then, after the result has been established, a recession of the left internal rectus. If there is still a residue of convergent strabismus after the adduction has been normalized, a resection or advancement of the right external rectus—or possibly of both external rectus muscles—should follow.

DISCUSSION

The patient has a low, isometropic refractive error. He has for no apparent reason acquired acutely a marked convergent strabismus with all the earmarks of concomitance. The left eye is habitually used for fixation; the adduction is excessive in both eyes; the abduction is normal. The patient has permanent spontaneous diplopia; the relative position and distance of the two images correspond to his angle of squint; the retinal correspondence is normal; there is no sign of suppression. When the angle of squint is compensated by prisms or in the synoptophore, there is no *horror fusionis*, but a rather high degree of binocular coöperation.

The diagnosis and the therapeutic course to be taken are clear. But two points remain unexplained. One is, why the patient whose visual acuity is normal

and equal in both eyes, and who is perfectly able to fixate with either eye, does not in any sense alternate and never spontaneously uses the right eye for fixation. The other question is why the strabismus has occurred at all in his case.

There is no known family history of strabismus; the ocular conditions do not predispose the patient for strabismus; no cause for the interruption of fusion could be found. While it is impossible to offer an explanation for the etiology of the strabismus in this case, similar observations can be quoted for comparison.

E. A. A., a boy 11 years of age, in good health, gave a negative ocular family history. Two months prior to the first examination the father had noticed that the boy's right eye turned in occasionally. The boy had never worn glasses; he had a low hyperopic refractive error and normal vision in each eye (R.E. = L.E. = +1.00D. sph. \approx +.50D. cyl. 90° = 20/20 under atropine). He showed an intermittent alternating convergent strabismus of 13 to 15 arc degrees with normal retinal correspondence and a slight excess of adduction in the right eye. There was no sign of any paralysis of the external ocular muscles. In the synoptophore the patient had normal binocular vision, although there was some suppression of the right eye. The refractive correction was given and the patient was not seen until a year later, at which time he reported that the strabismus had become much worse and that for the past three or four months the right eye had been turned in all the time. The angle of squint had indeed increased to 23 arc degrees; otherwise the condition was unchanged. A recession of the right internal rectus gave a good cosmetic and functional result.

S. S. M., a nun aged 25 years, reported

that she had noticed occasional diplopia and turning in of her eyes for four years previous to the first examination; for the past six months the strabismus and the diplopia had become permanent and the turning increased. The patient wore O.U. $-0.75D.$ sph., but an atropine refraction revealed R.E. = L.E. = $+1.50D.$ sph. = 20/20. There was no anomaly whatever in the rotations, but the patient had a very large angle of alternating convergent strabismus (approximately 30 arc degrees) with normal retinal correspondence. There was a great deal of suppression of the nonfixating eye. A bilateral resection with advancement of the external rectus muscles gave an excellent cosmetic and functional result.

Mrs. E. B. H., a woman aged 72 years, reported that 10 years prior to the examination she began seeing double during an attack of pneumonia and that the diplopia had persisted ever since. Both eyes were normal in every respect and had a visual acuity of 20/20 with a low plus sphere (R.E. = L.E. = $+0.25D.$

sph.). The patient had an alternating convergent strabismus of 10 arc degrees with normal retinal correspondence and without any anomaly in the rotations. She had normal binocular vision and good fusional amplitudes in the synoptophore. A resection with advancement of the left external rectus gave an excellent cosmetic and functional result. The patient has had no diplopia since. Two years after the operation an esophoria of 2^{Δ} for distance and $7-8^{\Delta}$ of exophoria for near were found.

The cases reported show that concomitant alternating convergent strabismus may occur more or less suddenly at any age. In none of these cases was there any sign of a paralysis of the external rectus muscles; all patients had a low refractive error and possessed undoubtedly full binocular vision prior to the onset of the strabismus. In only one did a disease that might account for its development precede the strabismus.

4 Webster Avenue.

SOCIETY PROCEEDINGS

EDITED BY DONALD J. LYLE

CHICAGO OPHTHALMOLOGICAL SOCIETY

December 20, 1943

DR. VERNON M. LEECH, *president*

CLINICAL MEETING

(Presented by the Department of Ophthalmology, Loyola University Medical Society)

ACUTE OPTIC NEURITIS, O.D.

DR. PAUL CARELLI presented M. P., a white girl, aged 23 years, who complained on December 5, 1942, of sudden severe frontal pain and headache which was relieved with aspirin. Three days later, on arising, she noted marked diminution of vision in the right eye. Examination on December 10th showed the vision R.E. was reduced to ability to count fingers at 1 foot; L.E. 1.2-1.

The fundus of the right eye showed the optic nerve swollen, the margins blurred. There were no hemorrhages nor exudates. The vessels were apparently normal. There was no improvement with correction of refractive error. The visual fields showed a central scotoma with peripheral contraction. Physical and laboratory examinations showed nothing significant with the exception of enlarged and chronically injected tonsils and cloudy sinuses.

The patient remained in the hospital for 13 days, during which time she received daily intranasal shrinkage packs for the first week; 4 intravenous typhoid injections; 6 injections of 1-c.c. thiamin chloride; 4 injections of nitroscleran. There was slight reduction of the swelling of the nerve. One month after onset, with weekly injections of thiamin and

nitroscleran, the edema had subsided, the disc was slightly pale, and the vision was unchanged. Tonsillectomy was performed. In February, 1943, the vision was 0.4 and the nerve head was definitely pale.

In March, three months after onset, the vision of the left eye suddenly decreased to 0.5 with central scotoma and partial upperquadrant defect. The previous treatment was repeated, with gradual improvement in vision. In June, 1943, the disc of the right eye was definitely pale; the disc of the left eye was normal. The vision was R.E. 0.8-4; L.E. 1.2-3.

ACUTE OPTIC NEURITIS, O.D.

DR. PAUL CARELLI said that A. T., a white woman, aged 28 years, gave a history of sudden loss of vision in the right eye, following headache and pain on movement of the eyes. Examination two weeks after onset showed vision R.E. 5/200; L.E. 1.2-4. The fundus of the right eye showed swelling of the nerve head, and blurring of the margins. There were no hemorrhages nor exudates. The left eye was normal. The physical and laboratory examinations were essentially negative except for slight cloudiness of both ethmoid sinuses and enlarged turbinates.

The patient remained in the hospital 10 days under treatment with typhoid injections, nitroscleran, thiamin, and salicylates, and thereafter was kept under observation. Three months after onset the vision in the right eye was 1.0. The disc was definitely pale. Six months later, following cessation of therapy, the vision again dropped to 0.6. Weekly injections of thiamin and nitroscleran were re-

sumed and vision returned to normal within one month.

MIKULICZ'S SYNDROME: RIGHT FACIAL PARALYSIS

DR. ROY RISER (in presenting the following three cases for Dr. Carl Schaub) said that Sister A. C. was first seen in January, 1943. She gave a history of 4+ severe dryness and 4+ redness of the eyelids; 4+ parched burning and dry tongue and difficulty in swallowing which had been present since August, 1942. There was bilateral 4+ enlargement of the parotid, submaxillary, and sublingual glands, and the patient complained of extreme pain. The Schirmer test was practically negative. The lacrimal glands were palpable under the superior orbital rim. The patient was given large doses (45 to 60 drops) of potassium iodide daily; pilocarpine sweats; and an eye wash to be used frequently as a substitute for tears; vitamin B and cod-liver oil.

In May, 1943, a right facial paralysis occurred and she went to the general clinic where a complete neurologic examination was made. This paralysis was probably due to the swollen glands.

When last examined in November, 1943, the glands were hardly palpable, the general condition was much improved, and the Schirmer test now showed tears.

BILATERAL POSTINFLAMMATORY LESIONS

DR. ROY RISER said that E. W., a man, aged 30 years, was shown before this Society in January, 1943. The history was of an attack of inflammatory edema in the right eye in December, 1939, which resulted in a large central atrophic area. The vision was 20/70—1. A second attack occurred in the left eye in February, 1941. Two lesions were found in this eye, in the upper outer portion of the macula, and a smaller pinhead-sized lesion immediately intrafoveal. Vision of

the left eye was 20/12 with correction.

At that time the condition was thought to be on a focal inflammatory or vascular basis. The patient was given typhoid injections; old tuberculin; and peripheral vascular investigations were carried out. Therapy has been continued with thyroid, theominal, vitamin C, and multiple vitamins.

In August, 1943, the left eye had another acute attack followed by an intense gray ischemic edema of the entire macular area. The vision was reduced to 1/200 and gradually returned to 20/40. Again in December, 1943, the patient suffered deep hemorrhages which reduced the vision to 2/200, from which it is slowly recovering. It is felt that the condition is angiospastic in origin, and in addition to the previous treatment, an allergic investigation will be made.

BILATERAL PARALYSIS OF SPHINCTER PUPILLAE

DR. ROY RISER said that Mrs. L. C. B., aged 46 years, was refracted under paraldrine on November 26, 1943. Thirty-six hours later she complained of migraine headache with marked decrease in vision in both eyes. On November 29th, there was severe pain in the right eye and head and a deep cloudy area in the center of the cornea of the right eye. The pupils were dilated, irregular, and fixed. The tension was normal. The vision was R.E. 0.1; L.E. 0.82. The condition gradually improved and the vision at this time was R.E. 1/5—2; L.E. 1.0. Because the findings simulated those of glaucoma, eserine drops were prescribed and gynergen injections daily were advised.

MARFAN'S SYNDROME

DR. J. R. FITZGERALD presented a man, aged 28 years, who was seen for the first time in April, 1943. He had been rejected

by the Army and was told that his eyes were not properly corrected.

The patient was 73 inches tall, slender, and somewhat stooped, and weighed 130 pounds. There was marked elongation of the bones of the extremities, particularly the distal phalanges. A slight kyphosis was present in the thoracic region, with marked pigeon breast. His face was slender, with fairly prominent mandible. There was marked absence of subcutaneous fat. No visceral changes were found. Mental development had been normal. Family and past history were negative.

The essential ocular findings consisted of an iridodonesis with incomplete symmetrical ectopia lentis in each eye. The pupils measured 3 mm. in diameter, were equal, and reacted well to light and accommodation. Tonometric readings were within normal range. No peripheral field changes were found. The vision was R.E. 20/100, corrected to 20/50 and J.3; L.E. 20/30, corrected to 20/20 and J.1. There were 16 prism diopters of exophoria present for near. No unusual fundus changes were noted.

This patient presented a well-marked picture of arachnodactyly or Marfan's syndrome, with demonstration of most of the classical features.

ESSENTIAL BLEPHAROSPASM WITH SURGICAL CORRECTION

DR. J. R. FITZGERALD said that this woman, aged 73 years, when seen for the first time in October, 1943, complained of inability to open her eyes, associated with painful spasm of the eyelids. At first the lid spasms were infrequent but they have increased during the past three years until she was unable to get about. She gave a history of an illness suggestive of encephalitis following influenza in 1918.

During the past two years she had had

considerable medical care, including five weeks' isolation under psychiatric observation. Alcohol injections of the parotid plexus of the facial nerve had given only temporary relief. Neurotomy of the temporal and zygomatic branches of the facial nerve had also failed, and resection of these branches had been suggested.

Ocular examination revealed a blepharospasm occurring in waves about 4 to 5 minutes apart, lasting 1 to 2 minutes. The spasms were so severe that the lashes disappeared behind folds of skin. No entropion was present. In periods between spasms the lids remained closed, leaving none of the lid margin structure visible. Voluntary attempts to open the eyes resulted in initiating a spasm. The use of pontocaine or cocaine solutions in the conjunctival sac did not change the pattern of the spasm. Ocular examination was possible only by the use of akinesia by the Van Lint or O'Brien methods, both of which were used. Essential ocular findings consisted of a compound myopic astigmatism, peripapillary choroidal atrophy, and a nuclear cataract. The vision was 20/50 in each eye with correction. Associated with the blepharospasm was a head nodding and facial twitching which was accentuated during the periods of lid spasm.

On December 6, 1943, a resection was done of 15 to 20 mm. of the temporal and zygomatic branches of the facial nerve at the exit from the parotid gland. This was followed by a parotitis which subsided promptly. On December 9th, a similar procedure was done on the left side, with uneventful recovery. On the right side, on the eighth postoperative day, a mucopurulent exudate appeared from the upper angle of the wound. This was followed by the appearance of saliva which drained out in considerable quantities when the patient was eating. It had been determined that the parotid duct was

patent and functioning. No sign of trauma or perforation of the gland was visible at the time of surgery. Either trauma or a parotid abscess which ruptured internally formed the basis of the fistula.

The result was extremely satisfactory to the patient. Spasm, which was still present in the corrugator muscle, did not result in complete closure. On digital attempts to open the lids, spasm occurred but the lids could be separated easily. The patient could voluntarily widen the palpebral aperture. The permanence of the result will be reported at a later date.

DR. SIGMUND AGATSTON, *presiding*

SYMPOSIUM ON THE RETINAL CIRCULATION

THE DEVELOPMENT OF THE CIRCULATION OF THE RETINA

DR. A. L. KORNZWEIG said that the development of the circulation of the retina in a human embryo divides itself naturally into three periods. The first period extends from the third to the fourth week. Numerous capillaries invade the retina, just as they do in the brain, but in the retina they disappear at the end of the fourth week.

The second period, which extends from the end of the first month to the end of the third month, is marked by an entire absence of blood vessels. The retina is nourished indirectly by the hyaloid artery and its branches.

The third period, which begins at the beginning of the fourth month and extends up to term, is characterized by the development of the definitive retinal

arteries and veins from the nerve head. The hyaloid system completely atrophies, but the hyaloid artery, up to the head of the optic nerve, becomes the central artery of the retina. The venous circulation is also established during this period.

Numerous anomalies of the retinal circulation are mentioned, among which are persistent hyaloid artery, remnants of Bergmeister's papillae, prepapillary vessel, anomalous artery or vein in the macular region, congenital tortuosity of the blood vessels, and the cilioretinal artery.

Slides showing the different stages in the development of the retinal circulation were demonstrated.

PHYSIOLOGY OF THE RETINAL CIRCULATION

DR. CHARLES ROSENTHAL reviewed the physiology of the retinal circulation with special emphasis on the mechanism of the arterial and venous pulsation of the retinal vessels. Both Bailliar's and Duke-Elder's method for determining the blood pressure of the retinal vessels was discussed. Some consideration was given to the capillary circulation and Puntenney's method for studying the systolic and diastolic pressure in the capillaries.

Upon reviewing the literature on the effects of chemical stimuli on retinal circulation, it was found that in 1934 Lambert devised a method for photographing and measuring the retinal vessels and reported the effects of adrenalin and nitrites. He found a vasodilation after the intravenous use of adrenalin and a vasoconstriction after the use of nitrites. Puntenney, in 1939, using a similar technique, found that no change took place in the retinal vessels after the intravenous injection of adrenalin or the use of nitrites. He found a definite vaso-

constriction after the use of mecholyl. In 1939, Cushick and Herroll found that tobacco and cold both caused vasoconstriction of the retinal vessels.

The contribution of angioscotometry to our knowledge of the retinal circulation was also reviewed. It was shown that anoxia caused a widening of the angioscotomata, whereas increased oxygen inhalation caused a narrowing of the angioscotomata. The oral administration of benzedrine likewise induced a narrowing of the angioscotomata, as did the use of tobacco, whereas the cold pressor test showed a widening of these scotomata.

CLINICAL STUDIES IN ANGIOSPASM

DR. ISADORE GIVNER read a paper on this subject which has been published in this Journal (1944, v. 27, Dec., p. 1408.)

OCULAR PATHOLOGY OF HYPERTENSION

DR. SAMUEL GARTNER presented a series of slides illustrating the various aspects of this subject.

Discussion. Dr. Henry Minsky stated that hypertensive fundus changes are proportional to the systemic blood-pressure readings, if one considers a basic or established level, disregarding fluctua-

tions due to added factors. He is attempting to determine and evaluate these arteriolar changes so as to develop a formula whereby the patient's established and intrinsic diastolic pressure can be estimated. At present this estimation depends on the subjective, clinical impressions of the observer.

Dr. Sigmund Agatston has claimed for years that the discovery of the cause of retinal arteriolar spasm would mean the discovery of the cause of hypertension. The ophthalmoscopic study is of primary importance as the microscopic findings comprise the final, secondary picture. Temporary spasm and closure of the vessels occur, and cases have been seen in which the actual reestablishment of patency was observed. Dr. Agatston has seen changes in caliber take place while studying fundi for periods as long as two hours and believes these vessels later show definite pathologic changes. The vascular occlusion interferes with the nutrition of the vessel walls, which are nourished by the blood they contain, and may result in hyalinization, narrowing, and fibrosis.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Lawrence T. Post, 640 South Kingshighway, Saint Louis 10, Missouri*; Society Proceedings to *Dr. Donald J. Lyle, 904 Carew Tower, Cincinnati 2, Ohio*. Manuscripts should be original copies, typed in double space, with wide margins.

Exchange copies of medical journals should be sent to *Dr. William H. Crisp, 530 Metropolitan Building, Denver, Colorado*.

Subscriptions, applications for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Miss Emma S. Buss, 5428 Delmar Boulevard, Saint Louis 12, Missouri*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE OPHTHALMOLOGIST'S RELATIONSHIP TO GROUP PRACTICE

It has become increasingly evident that profound changes are certain to take place in the practice of medicine within the next few years. Trends indicate that prepayment for medical care will rapidly become the rule rather than the exception and that group practice will occupy a much more important place in the near future than at any time in the past. The socialistic trend throughout the civilized world and the strong leaning of our own Government toward the left are important elements in this development. An essential factor for human well-being is the assurance of security in the oncoming

years. This can be obtained only by planning in the present. Economic security cannot be divorced from medical care. It is necessary to provide for every contingency that may interfere with the working capacity of the individual in the future, and one of these obviously is illness.

It is logical, therefore, that a plan to provide for the expenses of illness should be devised. Health insurance seems inevitable for most of the intelligent workers of the world. To maintain a good standard of health requires thorough examinations periodically. Specialists as well as internists must be called upon for such examinations, and although it is theoretically possible to act individualis-

tically in this matter, greater efficiency can obviously be achieved through a group of doctors working in a common center. An almost certain outgrowth of group examinations is group treatment.

There is, too, the demand of patients for thorough physical examinations entirely apart from the insurance matter. Some people are wise enough to appreciate the value of periodic examinations and have the tenacity of purpose to go through with them, but if these tests are to be other than such routine brief examinations as blood-pressure tests and urinalyses much time may be wasted in making appointments and waiting and walking. The public seems to like the group idea. People think that they are getting something complete and fine. Whether they are or not is less certain. Group practice can be either good or bad, depending essentially on whom the group comprises, just as in any other type of practice. The question primarily to be discussed here is not, however, the merits of group care, but the ophthalmologist's relationship to it.

The ophthalmologist's income is different from that of most other physicians in that it depends on multiple small fees from many patients. In other words, he must have volume. It has been the writer's practice to advise his students, almost all of whom plan to practice ophthalmology exclusively, not to settle in a city of less than 25,000 people, because he thinks that a community of less than that number will rarely support an exclusively ophthalmologic specialist. Most of the income is from fees for refraction, and probably one visit in three years would be a fair patient average. It requires no mathematical genius to compute the number of patients that must consult an ophthalmologist for him to earn a living.

Since we all hope for at least this, it

is clear that the ophthalmologist must do nothing that will reduce either his volume of business or his fee per patient visit, unless one or the other rises correspondingly to the lowering of the other. The truth is that in group practice he is in danger of reducing both, but especially of having the fee per visit lowered.

Another unpleasant possibility is that of change in the character of the practice. Most ophthalmologists see many patients sent to them by other physicians, and among these are found many of the more interesting cases, potentially operative and diagnostically stimulating. He may expect to lose much of this practice, for those who have referred patients to him as an individual are not so eager to do so when he is in a group, because they fear that he will be apt to send to others in his group patients who have been referred to him.

Most groups have been founded by internists or general surgeons, very few, if any, by ophthalmologists, and the internist or surgeon is usually regarded as the most important member of the group. Other specialists are relegated to minor roles. The ophthalmologist, about whose work the physician and surgeon know little, must accept one of these minor positions. Obviously his voice in the organization is proportionately small and his share of the income on a like basis. This does not, however, reflect the point of view of the people with regard to their eyes. They realize that on their eyes, more, perhaps, than on any other single sense, rests their happiness and ability to make a living. It is true that their physical and mental equipment must be functioning satisfactorily and that major ailments, such as an attack of appendicitis or an infection, may completely incapacitate them, so that at such times the surgeon or internist becomes all important; in general, however, they give relatively little thought to their general

physical condition until some ailment demands attention. From these facts it follows that the ophthalmologist, backed by the opinion of the community, has a strong conviction of his importance to the welfare of the people and is not prepared for the position which is usually assigned him in a group.

It has been the writer's experience that those of his students who have entered group practice have not been so happy as those who have practiced independently; in fact, most of them have not remained for long in a group. A further reason for this may be that when a group attains a large size and a large number of patients is seen, the ophthalmologic specialty, small as it is, is subdivided, some ophthalmologists being assigned to perform refractions, others to surgery and treatment, others to the study of fundus conditions, so that the danger of having a narrower viewpoint increases and the specialist may correctly be described as one who knows more and more about less and less.

All of the picture, however, is not dark. The ophthalmologist can refer patients within the group without having to think constantly of the cost to the patient. He is usually relieved of the onerous task of assessing fees and trying to collect them. The individual is his own hardest taskmaster, and undoubtedly in group-practice work hours are shorter and there is less stress on the physician.

To mention another disadvantage, and really a very important one to most democratic people, is the giving up of individual independence to some degree. Though it is true that the physician practicing alone is the servant of every one, he is not the servant of any particular one nor of a small group. His practice does not depend on the action of any one person or small number of persons. Certainly, if he finds the group association

incompatible, he is at liberty to withdraw, but this is not an easy thing to do. Much of the practice will have come to him because of his group association and in many cases he is only the ophthalmologist of the group, is scarcely known by name to the patients, and is often quickly forgotten by them, for they recall only the name of the clinic. In other words, he cannot take his practice with him if he decides to leave. There is the further disadvantage that he may not be able to choose the time of his withdrawal but may be asked unexpectedly to sever his connection with the organization.

Undoubtedly, there are many ophthalmologists who have found great happiness in group practice and equally surely this form of handling patients will become increasingly prevalent. So it behooves all physicians to give serious thought to the matter. This, as every other form of medical care, will, in the long run, stand or fall as measured by its success in the care of patients. The extent of the turnover to group care will depend on this; but though the trend seems definitely in this direction there will probably always be a place for those who wish to practice independently.

Lawrence T. Post.

"OPHTHALMIC ASSOCIATES"

There was a shortage of ophthalmologists long before the current war. This shortage is a continuing trend. The problem of distributing medical care in this field is not likely to be met by conventional measures and methods now in sight. There probably are a number of partial solutions, each of which would contribute toward solving the problem. Increasing or doubling the number of eye physicians in training at teaching centers would partly remedy the need.

Another real contribution toward more physicians in our field would follow the adoption of a new definition of what constitutes an ophthalmologist—the recognition of two groups in the speciality: (a) the medical ophthalmologist, concerned with other than the major surgical aspects of practice, and widely distributed in both small and large communities; (b) surgical ophthalmologists, fewer in number, more elaborately trained in the surgical field and distributed in centers for surgical treatment. This is actually the situation today in practice, although its benefits from the standpoint of wide distribution and safe practice are limited because teaching is not directed into these dual channels and no provision is made for officially recognizing more than one kind of ophthalmologist.

A third method of amplifying eye care, both medical and surgical, is by creating a new professional personnel. A move toward this end is seen in the orthoptic-technician group. Their well-thought-out program has established a national organization of technicians under an orthoptic council, but too few are trained in this field to meet the demands. This is partly due to war dislocation and lack of training centers, but also a certain lack of appeal is to be found in this field because of its limited scope. By widening the base of the orthoptic group, or by creating another professional group, there could be evolved an exceedingly important personnel concerned with increasing medical care of the eye patient. This group, "Ophthalmic Associates," should include in its domain measurement of refractive errors, perimetry, orthoptics, some bacteriology and other laboratory techniques, office and hospital assistance. In practice with this group the responsibility of the care of the eye patient remains with the eye physician. This new

group would have a professional standing and association with the physician and would extend both his range and improve his standards. To bring this association to its proper high level requires mutual understanding and respect between both physician and ophthalmic associates, somewhat as medicine marches along with the biologic sciences as co-workers in overcoming the problems of disease. It is not a matter of dominance, but of participation and responsibility. This suggested agency—that of "Ophthalmic Associates"—offers a professional field for those who will take the necessary training. To meet satisfactory educational standards in this group would require four years of college-level training, two in the literary school and two in the technical subjects, leading to a B.S. degree. This curriculum could be supplied by the widely distributed existing educational agencies, but a more active participation by the medical profession in the teaching program would be necessary during the last two years. The medical and educational professions have yet to meet their full responsibilities in this educational field.

Many eye physicians have in their office or hospital practices individuals, self or preceptor trained, whose services have become indispensable and who reduce the onus of the routine. They greatly extend the coverage of medical practice. One or several Ophthalmic Associates working with the physician would greatly enlarge his capacities to meet his responsibility of medical care.

Parker Heath.

Detroit, Michigan

WHY CORRECT HYPEROPIA?

To most ophthalmologists the answer to this question is so obvious as to make

the question itself appear ridiculous. Yet it is a question asked, although in less technical language, by many patients; and it is a question which still persists in the minds of some ophthalmologists and some refracting opticians, and very certainly in the minds of a good many general physicians.

Usually, the question is stated in the following form: Why should we prescribe glasses, especially for constant use, if the patient can see perfectly without correction? In a case in which the question was recently overheard by the present writer, the patient, a woman in the twenties, had complained of persistent headache.

The headache in such a case appears basically to be due to fatigue. It is not so very important whether we think of this fatigue as residing in the muscle of accommodation or in the nerves which control that muscle. Any muscle or set of muscles, and any set of nerve fibers controlling such muscular unit, demands frequent intervals of relaxation. Even the muscles of the heart, that great organ which comes nearest to a state of constant activity, have their rhythmic intervals of relaxation.

In dealing with the tiny intrinsic muscular system of the eye, it is true that different individuals vary greatly in their tolerance or intolerance for continuance performance of the necessary act of accommodation. Many persons with appreciable amounts of hyperopia go through much of their lives with never a visit to an ophthalmologist or an optician, and are unwilling to admit that they have ever experienced fatigue due to use of the eyes. Some of them even assure us that they use their eyes very little, and are rather taken aback when told that during the usual sixteen-hour waking day the eyes are constantly used, although perhaps not for near work.

During distant vision the ametropic eye is approximately at rest, so far as use of the ciliary muscle is concerned, but the hyperopic eye must make an effort of accommodation even in looking at distant objects. Thus, except during complete closure of the eyes or the very fractional intervals provided by the act of blinking, the hyperopic eye is deprived of the opportunity for complete relaxation. The same is true of the hyperopic eye whose refractive error is only partially corrected.

Many persons develop symptoms of fatigue or eyestrain from very small errors of hyperopia. It seems probable that no one with even a low uncorrected hyperopia can attain in all circumstances, and throughout the working day, that maximum of efficiency of which he would be capable if the hyperopia were completely corrected. The mere lack of opportunity for complete ocular relaxation during the waking hours would seem to point to this conclusion.

It is true that many hyperopic school children offer no complaint of discomfort, and are either unwilling, or are not permitted by their parents, to wear glasses, even after some question related to school activity or general health had led to a diagnosis of hyperopia. It is also true that, in the presence of a prejudice against the wearing of glasses, physicians have suggested technique for getting along without hyperopic corrections. However, there can be little doubt that Nature exacts some penalty for such procedures, and that, either in very minor or in much greater degree, the career of the individual is modified by refusal of the refractive correction.

If failure to correct a low hyperopic error may produce an adverse effect in the life of an individual, what reason can there be to suppose that leaving undercorrected a like amount of hyperopia

in another individual with a much greater total error will not also be capable of doing mischief? This is a problem for serious consideration by those who are in

the habit of giving only partial corrections for the larger amounts of hyperopic error.

W. H. Crisp.

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |

GENERAL METHODS OF DIAGNOSIS

Bedell, A. J. **Ophthalmoscopy and the diagnosis of human illness.** *Amer. Jour. Ophth.*, 1945, v. 28, Feb., pp. 139-147.

Gray, C. C., and Moor, W. A. **Serologic studies in acute eye diseases.** *Amer. Jour. Ophth.*, 1945, v. 28, Feb., pp. 180-186. (One table, references.)

Oliveres, Antonio. **Retinometric loupe.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, Jan.-Feb., pp. 96-97.

The loupe presented is composed of two plano-convex lenses of +7.50D. strength. On the plane surface of one of the lenses is engraved a reticule, each square of which is 5 mm. wide. The two lenses are united by means of Canada balsam. The loupe is used in indirect ophthalmoscopy with the inverted image, and makes the measurement of retinal lesions easy.

THERAPEUTICS AND OPERATIONS

Brücher Encina, René. **Nonspecific desensitization treatment in some eczematous eye diseases.** *Arch. de Oft. de Buenos Aires*, 1942, v. 17, Dec., p. 748.

In a series of 16 patients with various manifestations of ocular allergy in which specific allergens could not be found, the author used autohemotherapy with remarkable success. First, 10 c.c. of calcium-bromolactobionate (calcibronat) was given intravenously, and then, before withdrawing the needle, 10 c.c. of blood was aspirated into the same syringe, and quickly injected intramuscularly in the buttock. Marked improvement was obtained in 14 patients. A correct diagnosis is of paramount importance for therapeutic success, and tuberculous, syphilitic, and focal-infection cases should be excluded from this method of treatment.

Plinio Montalván.

Cogan, D. G., and Hirsch, E. O. The cornea. 7. Permeability to weak electrolytes. *Arch. of Ophth.*, 1944, v. 32, Oct., pp. 276-282.

Experiments conducted on excised corneas indicate that the permeability of various weak organic electrolytes is a function of the degree of dissociation of the electrolyte. The preparations tested include analine, salicylic acid, atropine, pilocarpine, and ephedrine. It was found that the organic bases penetrated the cornea, while their salts did not. This corroborates the previous observation that the corneal epithelium and endothelium are barriers to substances not soluble in fats. The free base has the power of penetrating the epithelium-stroma combination, while the salt penetrates the stroma only. Conjunctiva-sclera combinations behaved in a similar manner. Experiments on the intact rabbit cornea in vivo indicate that the permeability of analine is a function of dissociation.

The permeability of an alkaloid through the cornea may be predetermined if one knows the dissociation constant and the solubility properties of the drug. A knowledge of these factors influencing permeability may make it possible to select more suitable drugs for ocular therapeutics. Other factors, however, apply some limitations to the selection of the more permeable agents. Thus many alkaloids are unstable in aqueous solution unless acidified. In addition, the buffer action of the tears will determine the hydrogen-ion concentration of a weak solution as soon as it is instilled. Thus there is no advantage in employing solutions of alkaloid bases instead of the salts, and considerable disadvantage may arise from decomposition of the base. (3 tables, 4 figures, references.)

Cordes, F. C. Typhoid-vaccine therapy; an unusual reaction. *Quarterly Bull. Northwestern Univ. Med. School*, 1944, v. 18, no. 3, pp. 184-192.

The author calls attention to the risks which one may incur following intravenous typhoid-vaccine therapy.

A 59-year-old woman developed acute congestive glaucoma. Iridectomy was performed. Three months later the eye again became red and painful, this time from acute iridocyclitis. Physical examination was negative except for the faintest possible trace of albumin in the urine. She received 7 million bacilli of a typhoid vaccine intravenously and 48 hours later 15 million bacilli. After an initial chill the temperature suddenly rose to 43°C. and hovered for two hours at 42°C. The patient lost consciousness and became incontinent and cyanotic and there was a large amount of emesis. Only a small amount of urine was obtainable by catheterization. This showed 4+ albumin and the centrifuged sediment was packed with white and red blood cells. On the third day the blood pressure rose to 200/100 mm. Hg. The patient eventually recovered.

The unusual reaction took the form of the hepatorenal syndrome. This consists of drowsiness or somnolence, emesis, anuria or oliguria, icterus, fever, hemorrhages in the mucous membranes, rise in blood-nonprotein nitrogen and creatine, hematuria, albuminuria, and semicomatose, frequently with decreased CO₂ combining power of the blood plasma.

Two forms of the syndrome are described, rapid hyperpyrexia, liver death or liver shock, and the delayed or protracted form of the liver-kidney complex. The former is fatal in one to three days. In the latter death is delayed for

12 to 14 days, but some cases recover. (References.) R. Grunfeld.

La Rocca, V. Intraocular injection of penicillin in ocular infections. *Amer. Jour. Ophth.*, 1945, v. 28, Feb., pp. 183-186. (2 figures.)

Law, F. W. *Ophthalmology*. The Practitioner, 1944, v. 153, Oct., p. 233.

The author describes recent advances and modern trends in ophthalmic therapy. Local application of sulfa drops in various types of external diseases of the eye he has not found more advantageous than use of other anti-septics. Sulfanilamide taken by mouth is of no value in iritis, iridocyclitis, or choroiditis. It is of proved value in ophthalmia neonatorum and in early cases of endophthalmitis. Penicillin is a very promising drug in blepharitis and in superficial infective conditions.

In corneal injuries with prolapse of the iris corneal sutures are preferred to a conjunctival flap, because apposition of the wound edges is more accurate. The method has the disadvantage that the sutures may cause local infiltration in the avascular cornea, with permanent loss of vision and even ulceration and sloughing.

In phlyctenular ophthalmia, unless the condition of the lungs forbids it, a general ultraviolet-light bath is of proved value. Ultraviolet light is rarely used nowadays for local therapy, although recurrent corneal erosions heal well under it.

Any kind of intraocular inflammation is helped by the application of diathermy, of which the most effective form is the ultrashort wave. It is advised mostly in glaucoma, choroiditis, and postoperative reactionary endophthalmitis. Diathermy is so much more efficient than any other form of heat

therapy as to suggest that some hitherto uninvestigated electrical effect on living cells and tissues plays a part.

Other topics discussed are: removal of nonmagnetic foreign bodies, enucleation of dangerous eyes, pentothal anesthesia, and vitamin therapy.

Mietus, C. A. Ocular therapy with penicillin used topically, intraocularly, and systemically. *Amer. Jour. Ophth.*, 1945, v. 28, Feb., pp. 173-179. (References.)

Milner, J. G. Penicillin in ophthalmology. *Brit. Med. Jour.*, 1944, Aug. 5, pp. 175-178.

This report covers a series of cases investigated by many observers who give in tabulated form the results obtained in different types of disease and infection, and the doses employed. The drug was used in liquid (500 Oxford units per c.c.) or in ointment (100 Oxford units per gm.). The drops are potent for four hours and the ointment for six hours. The frequency of treatment is to be regulated accordingly. The observers agree that penicillin affords the best results in blepharitis. There seems to be some difference of opinion as to its value in cases of acute conjunctivitis. Other definite indications for the use of penicillin are found in corneal ulcers, dacryocystitis, recurrent styes and chalazions, and immediately after operative procedures. It is also valuable as a prophylactic in cases of injury.

M. Lombardo.

O'Brien, C. S. Random observations on ocular surgery. *Quarterly Bull. Northwestern Univ. Med. School*, 1944, v. 18, no. 3, pp. 199-203.

In operating for cataract in children, juveniles, and young adults, a prelimi-

nary needling followed within a few days by linear extraction is preferred to repeated needling. The incision for cataract extraction is made with a keratome and scissors. In extracapsular extraction it is advisable to use capsule forceps rather than the cystotome, because the former removes a larger portion of the capsule and lens epithelium. If, after the lens has been delivered and the sutures tied, the iris has a tendency to prolapse it can be kept in position by injection of air into the anterior chamber. If discission fails to make a good opening in a secondary membrane, a small opening at the limbus will allow one to insert a sharp iris hook so as to pull out the membrane and snip it off with scissors.

When glaucoma simplex and cataract exist together Lagrange sclerectomy is combined with cataract extraction. Following any operation for glaucoma the eye should be massaged twice a day for several weeks. The incision for a basal iridectomy should be made with a Graefe knife and not with a keratome, because one cannot make an incision in the chamber angle with the latter.

The results are better if the operation for strabismus is deferred until retinal correspondence is made normal. It seems preferable to correct an ordinary squint by a two-stage operation.

In enucleation it is well to suture the recti muscles with a purse-string silk suture, inserting the suture at the end of each muscle just before the tendon is severed. Tying the suture immediately after the globe is removed will assist greatly in hemostasis.

R. Grunfeld.

Heat and cold have been used in ocular therapeutics since antiquity. Heat produces a vasodilatation of the tissues which not only affords comfort but also stimulates repair by accelerating metabolism and leukocytosis. It is recommended for mild keratitis, mild blepharitis, acute conjunctivitis, corneal ulcer, and many intraocular and lid conditions. Cold has an analgesic and therapeutic effect, acting largely through vasoconstriction. It is especially valuable for the relief of lesions produced by physical or chemical trauma, early conjunctivitis, blennorrhoea, and acute trachoma, and for post-operative care.

Various methods of applying heat and cold to the eye have been described. Many of these methods require such elaborate equipment or are so troublesome that their usefulness is restricted. The author describes the application of heat by means of a wooden household spoon encased in cotton. The bowl of the spoon is filled with cotton, and cotton also is applied to the back of the spoon. A 5 cm. gauze bandage is wrapped around the cotton in the form of a figure 8 and securely tied. The wrapped spoon is dipped in a basin of hot water, the excess of water shaken off, and the spoon is then applied to the eye. This is repeated as soon as the cotton cools. The author finds this method simple, convenient, and effective. Cold compresses may be applied to the eye by means of the wooden spoon or, simpler, by application of cotton that has been dipped in a mixture of water and ice. (2 photographs, references.) John C. Long.

McFarland, R., Halperin, M., and Niven, J. Visual thresholds as an index of physiological imbalance during anoxia. *Amer. Jour. Physiology*, 1944, v. 142, Oct. 1, p. 328.

The differential sensitivity of the human fovea was studied in relation to light intensity under normal oxygen tension and during a constant degree of oxygen deprivation (10.8-percent oxygen) in a low-oxygen chamber. Final measurements were made while the subjects breathed 100-percent oxygen through a nasal catheter. Nine subjects were used in these experiments. The manner in which the effect of anoxia on differential thresholds varies with the degree of oxygen deprivation

was studied on two subjects. The changes in visual sensitivity are plotted in relation to time, decrease in arterial oxygen saturation, and equivalent altitude, corresponding to the oxygen tension. The increase of the differential threshold is initially proportional to loss of arterial-oxygen saturation, but then tends to level off so that smaller increases result from further losses. The changes in the differential threshold plotted against equivalent altitudes are described with a sigmoid curve. Changes in visual sensitivity are discussed as an index of physiologic imbalance in the organism.

Edna M. Reynolds.

Traquair, H. M. Headaches, giddiness, and eyestrain. *The Practitioner*, 1944, v. 153, Sept., pp. 166-171.

The writer states that probably less than ten percent of headaches are due to ocular causes. He discusses the features of headaches as to their location, character, periodicity, and duration, the age of the patients, social, occupational, and sex incidences, and visual symptoms. The chief factor in the production of ocular headaches is the maintenance of binocular vision. If the vision is good in one eye and moderately bad in the other, headaches may be caused, for in this case binocular vision is difficult; but if one eye is amblyopic so that it cannot participate actively in vision headache is unlikely to result. In some cases the dissociation of accommodation and convergence renders maintenance of binocular vision difficult. The general condition of the patient's health, the physical and nervous and mental states, may be determining factors; feeble physique and resisting power, neuropathic disposition, anemia, constipation, inadequate or improper diet, lack of proper rest, are important elements in patients of hypersensitive nature. M. Lombardo.

4

OCULAR MOVEMENTS

Adrogué, E., and Re, B. V. A case of voluntary nystagmus. *Arch. de Oft. de Buenos Aires*, 1942, v. 17, Dec., p. 717.

The authors describe the clinical picture of voluntary nystagmus and discuss the pathogenic mechanism and differential diagnosis, giving a résumé of all the cases they could find in the literature. They report a case of voluntary nystagmus observed in a 28-year-old man who could produce at will rapid oscillatory movements of the eyes

in any position of gaze. The maximum speed of movement was from two to three oscillations per second, with a displacement of the eyes of 2 to 3 mm. The optic nerves showed colobomatous pits of the papilla, more marked in the left eye, with an extensive bilateral field defect involving the upper nasal quadrants. After twenty to thirty seconds of oscillatory movements, the patient complained of marked ocular fatigue, a point that the authors emphasize as typical of voluntary nystagmus. (Fundus pictures, visual-field chart, bibliography.)

Elliot, A. J. Congenital deficiency of abduction of the eyes (Duane's syndrome). *Jour. Canadian Med. Services*, 1944, v. 1, pp. 437-443.

The author presents three cases of Duane's syndrome, a condition which has at times been confused with various neurologic lesions. After referring to the historic aspects of this complex, the symptoms of retraction of the globe, narrowing of the palpebral fissure, and ptosis are explained. The

only treatment recommended is a moderate recession of the internal rectus if marked strabismus or diplopia is present.

Francis M. Crage.

Kino, F. F. Eye movements in electrical-shock procedure. *Jour. Mental Science*, 1944, v. 90, April, p. 592.

Observations were made of the eye movements resulting from symmetrical, equal, and simultaneous stimulation of the frontal lobes in the electric-shock procedure. In the postconvulsive or last stage of the four-stage-shock picture a forceful lateral conjugate deviation was noted as a constant feature, characteristic of a given individual. This individual pattern of eye deviation was uninfluenced by age, sex, or type of mental disorder.

Francis M. Crage.

Regan, W. W., Gregory, P. W., and Mead, S. W. Hereditary strabismus in cattle. *Jour. of Heredity*, 1944, v. 35, Aug., p. 233.

Normal at birth, several animals were found to manifest convergent strabismus when 6 to 12 months old. The degree varied, being so severe in some mature animals as to greatly impair vision. Abnormal bulbar protrusion existed in some. Inherited as a result of introduction into the herd of two unrelated bulls, the occurrence promptly stopped after use of homozygous normal bulls.

Smelser, G. K. The oxygen consumption of eye muscles of thyroidectomized and thyroxin-injected guinea pigs. *Amer. Jour. Physiology*, 1944, v. 142, Oct. 1, p. 396.

The oxygen consumption of the extraocular muscles in normal guinea pigs is much higher than that of the

other muscles studied. This difference is less in the muscles of thyroxin-treated animals. The effect of thyroid hormone on the water content of muscle tissue appears to vary in different muscles, and to be entirely separate from its effect on their metabolism. Although the thyroid hormone markedly increases oxygen consumption of the diaphragm, it has very little effect on that of eye muscle. This suggests that the enzyme systems which are the site of action of the thyroid hormone are present in variable amounts, or vary in activity, in different muscle tissues.

Theodore M. Shapira.

Swan, K. C., and Laughlin, E. Binocular orthoptic training for amblyopic patients. *Arch. of Ophth.*, 1944, v. 32, Oct., pp. 302-303.

The generally prevailing concept that visual acuity of 6/15 or better is essential for orthoptic training no longer applies. The peripheral fields play a predominant role in fusional movements. Focal fixation is desirable so that the cover test may be utilized for adjustment of orthoptic instruments. If it is not present, illuminated instruments may be adjusted so that the corneal reflexes are symmetric. In patients with poor visual acuity due to a central scotoma, training must be directed toward peripheral fusion.

Orthoptic targets containing fine details are of little value for this purpose. Simple disc and ring targets subtending angles larger than the central scotoma are applicable. In cases of eccentric fixation due to anomalous retinal correspondence no attempt should be made to develop fusional movements until normal correspondence has been developed. In those cases the ring targets should be used along

with occlusion of the eccentrically fixating eye to establish normal correspondence. The authors state that development of peripheral fusion assures the patient a permanent correction of the deviation and in some instances a partial return of central vision in the amblyopic eye.

Walsh, F. B. *Myasthenia gravis and its ocular signs: a review.* Amer. Jour. Ophth., 1945, v. 28, Jan., pp. 13-33; also Trans. Amer. Ophth. Soc., 1943, v. 41, pp. 556-624. (9 illustrations, bibliography.)

Yaskin, J. C., and Oller, C. I. *Oculomotor paralysis: some practical considerations from the anatomic, etiologic, and clinical standpoints.* Clinics, 1944, v. 3, Oct., p. 693.

Etiologic diagnosis of third-nerve paralysis is at times extremely difficult. Frequently it is the "earliest monosymptomatic expression" of some obscure systemic disturbance or a primary symptom of some brain lesion. The authors mention the most common pathologic states giving rise to the paralysis.

Anatomic, clinical, and etiologic considerations are discussed, with tables and diagrams. Seven illustrative cases include glioma, multiple sclerosis, and Benedict's syndrome.

Francis M. Crage.

Young J. H. *The effects of faradically induced currents upon the extrinsic and intrinsic ocular musculature.* Brit. Jour. Ophth., 1944, v. 28, Oct., pp. 488-502.

To study the clinical effect of the faradic currents upon the extrinsic and intrinsic muscles of the eye, the author performed a series of experiments upon

himself. Faradic stimulation of the left internal rectus was carried out, using the Smart-Bristow coil. The Maddox Wing test was used to register the amount of contracture of the internal rectus, while the degree of spasm of the ciliary muscle was estimated by the strength of the minus lens required to render the left eye emmetropic for distance.

Three important ocular signs, namely exophthalmos, nystagmus, and spasm of accommodation were produced. The experimental signs and symptoms are listed and the physiology of the reactions is discussed. The author feels that, with general anesthesia, faradism should prove useful in treating various muscular anomalies resulting from war trauma and also in the diagnosis and prognosis of ocular-muscle lesions. CONJUNCTIVA

Gardiner, P. A. *Observations on the transparency of the conjunctiva.* Brit. Jour. Ophth., 1944, v. 28, Nov., pp. 538-554.

With a view to defining some of the normal appearances of the conjunctiva and to elucidating the causes of deviation from the normal, a large group of subjects was examined. These were of both sexes, of different nationalities, living under different climatic conditions, and on different diets. The age range was from 9 to 37 years. Examination was made with the slitlamp with a wide beam slightly out of focus, to give bright diffuse illumination.

The transparency was assessed by noting the relative visibility of the deep vessels on the sclera. In subjects in whom the transparency was affected

by the presence of pingueculae or by diffuse hyaline degeneration, the areas thus involved were ignored and the transparency of the unaffected parts was recorded. A total of 1,892 men, 434 women, and 591 children were examined.

Every degree of transparency was represented in the adults, but in the children the conjunctiva was found to be opaque or opalescent. It is a normal phenomenon for the conjunctiva to increase in transparency between the ages of 9 and 37 years. The females showed constantly a more transparent conjunctiva than the males between the ages of 9 and 27 years.

Nutritional factors were found to play a part in influencing the transparency of the conjunctiva. A poor diet is accompanied by a relatively transparent conjunctiva and a good diet by a relatively opaque conjunctiva. Addition of vitamin A to the diet caused no change in the transparency of the conjunctiva. No change was seen in cases where ascorbic acid was added to the diet, but the addition of liver caused a noticeable increase in conjunctival opacity and an appreciable decrease in corneal vascularization.

Clinically, a transparent conjunctiva in children and young adults should be regarded as abnormal and should lead to investigation into possible dietary deficiency or metabolic disturbances. (13 tables, 4 graphs, references.)

Herraiz Ballester, Leopoldo, and Jolly, C. H. **Nonseasonal allergic conjunctivitis.** *Arch. de Oft. de Buenos Aires*, 1942, v. 17, Dec., p. 759.

The authors report two cases of allergic conjunctivitis characterized by itching, sensation of foreign body, photophobia, lacrimation, and marked

conjunctival injection, with scanty discharge. There were no follicles or papillae present, and instillation of adrenalin produced considerable relief. Evidence of inhaling allergens in the form of vegetable fibers, animal hair and dandruff, house dust, and atmospheric dust was discovered in each case, and vaccine containing these substances produced rapid and permanent cures. Plinio Montalván.

McNair, S. S. **Gonorrheal ophthalmia.** *United States Naval Med. Bull.*, 1944, v. 43, Sept., p. 532.

The author describes two cases in which gonorrheal ophthalmia was presumably contracted by use of the same pair of binoculars which had been infected from an unknown source. The left eye became affected in both persons at the same time. In spite of early treatment with sulfathiazole and penicillin, one patient lost his eye.

R. Grunfeld.

Rados, Andrew. **Epidemic keratoconjunctivitis and virus diseases of the eye.** *Arch. of Ophth.*, 1944, v. 32, Oct., pp. 308-329.

This article is a comprehensive review of the virus and rickettsial diseases of the eye. One of the diseases with which ophthalmic symptoms commonly occur is encephalitis. This may result in paralysis and spasms of the ocular muscles as well as retrobulbar neuritis and papilledema. Mumps may be responsible for keratitis, dacryadenitis, scleritis, uveitis, neuritis, and ocular palsies. Varicella has been

known to produce corneal lesions. Recent observations indicate that lymphogranuloma venereum may involve the eye. Gregg and others have recently shown that rubella in early pregnancy produces multiple congenital abnormalities in the offspring. These abnormalities include microphthalmos and cataract as well as systemic conditions such as heart defects, microcephaly, and deafmutism.

The rickettsias are apparently pleomorphic bacteria adapted to arthropod tissues. They are considered to belong to an intermediate class between viruses and bacteria. Ocular complications are observed with typhus. Mild conjunctivitis occurs with Rocky Mountain spotted fever. Severe inflammatory complications in the anterior segment of the eye have been observed in tsutsugamushi fever.

Viruses, like the rickettsias, are linked with living cells, either in the body or in cultures containing living cells. They are not capable of reproduction in the absence of living tissue. The nature and characteristics of viruses are discussed in considerable detail.

The first epidemic of epidemic keratoconjunctivitis recorded in the literature appeared in 1889 in Vienna. Epidemics have since occurred in Bombay, Madras, Malaya, Tasmania, Calcutta, Germany, and the United States of America. Details of the clinical findings in the various epidemics are recorded. It is thought that epidemic keratoconjunctivitis is caused by a virus related to the herpes virus or to a similar filterable virus. The disease has been transmitted to human volunteers and the etiologic agent can be grown in the living chorioallantois of chicks. The question whether superficial punctate keratitis and nummular

keratitis are two varieties of epidemic keratoconjunctivitis or are distinct diseases will require further investigation.

The numerous investigations conducted to determine the cause of trachoma are reviewed. The steps in the study of inclusion bodies are given in some detail. The rickettsial origin of trachoma has been advanced by some observers and denied by others. It is now assumed that trachoma is caused by a virus and that this virus is similar to the one that causes swimming-pool conjunctivitis and inclusion blennorrhea.

Herpes simplex was first transmitted experimentally to the scarified cornea of rabbits by Grueter in 1912. The filterability of the herpes virus has since been demonstrated. The virus of herpes zoster is thought to be possibly identical with, or at least closely related to, that of varicella. The lack of susceptible experimental animals has prevented its extensive study. The etiologic agent of molluscum contagiosum is filterable and may be multiplied in the chorioallantoic membrane of hens' eggs. Inclusion bodies are found in the epithelial lesion. The virus of warts is also filterable but as yet it has not been cultivated. (Bibliography.)

Roethli, A. F. de. Congestion in the upper quadrant of the bulbar conjunctiva, a sign of focal infection? Quarterly Bull. Northwestern Univ. Med. School, 1944, v. 18, no. 3, pp. 193-198.

The author describes a new sign, the upper-quadrant sign, which he observed in 15 persons, in 13 of them bilaterally. The patients complained of a mild burning sensation in the eye, scratchy feeling, and lacrimation. The eyeball seemed to be normal except for a net of dilated vessels of the bulbar con-

junctiva above the cornea. The episcleral vessels were not involved and the palpebral conjunctiva only rarely.

The sign seems to point to a focal infection, for in all but one of these cases foci of infection were present. The author applies the toxin-allergy theory of endogenous uveitis to explain the upper-quadrant sign. (Eleven case histories.)
R. Grunfeld.

Sorsby, A., Hoffa, E. E., and Young, E. N. **Virus ophthalmia neonatorum.** Brit. Jour. Ophth., 1944, v. 28, Sept., pp. 451-457.

A study of 28 cases of inclusion blennorrhea among 269 cases of ophthalmia neonatorum treated at White Oak Hospital from January 1, 1942, to December 31, 1943, is reported. The diagnosis was made by finding inclusion bodies in scrapings from the conjunctiva. One of the 28 cases could hardly be designated as ophthalmia neonatorum since the ophthalmia occurred in a boy aged two years. The smear and culture showed an abundance of *Staphylococcus aureus*. Of the remaining 27 cases, no organisms were present either in the smear or the culture in 24; one showed inclusion bodies and Koch-Weeks bacilli; and another showed inclusion bodies and hemolytic streptococci.

Apart from a later onset in most cases, but not in all, inclusion blennorrhea has no distinguishing features from microbial ophthalmia neonatorum, either in its course or in response to sulfonamide therapy. In five out of 25 mothers of infants with inclusion blennorrhea, cervical scrapings showed inclusion bodies. (5 illustrations, references.)

Edna M. Reynolds.

Vila-Coro, Antonio. **Severe purulent**

conjunctivitis of the newborn. Arch. de la Soc. Oft. Hisp.-Amer., 1944, v. 4, Jan.-Feb., pp. 18-25.

Four cases of severe purulent conjunctivitis of the newborn are reported. The affection has all the characteristics of a severe gonorrheal ophthalmia and invariably involves the cornea. Perforation usually ensues. In a few cases panophthalmitis results. No causative organism has been found, but it is supposed that a virus is the noxious agent. The course of the disease is not altered by any known treatment.

CORNEA AND SCLERA

Alpert, D. R. **Intraocular injection of penicillin in the case of ring abscess of the cornea.** Amer. Jour. Ophth., 1945, v. 28, Jan., pp. 64-67. (References.)

Castroviejo, Ramón. **Keratetectomies for the treatment of corneal opacities.** Trans. Amer. Ophth. Soc., 1943, v. 41, pp. 222-238. (See Amer. Jour. Ophth., 1944, v. 27, Dec., p. 1455.)

Chesney, A. M., and Woods, A. C. **Further observation on the relation of the eye to immunity in experimental syphilis. 2. The development of immunity after primary intracorneal inoculation.** Jour. Exper. Med., 1944, v. 80, Nov. 1, p. 357.

Two experiments are reported in which an attempt was made to determine the extent to which a primary syphilitic infection of the cornea in rabbits is followed by the development of a local corneal immunity, by the generalization of the virus, and by the development of a general immunity to the infection. Female rabbits were in-

oculated intracorneally with a virulent strain of *T. pallidum*, and the disease was allowed to run its course until the lesions which had developed at the site of inoculation had healed spontaneously. Transfer of popliteal lymph nodes from half of the group to normal male rabbits proved them infected in almost every instance demonstrating generalization of the syphilitic infection after intracorneal inoculation. All animals were treated with arsphenamine after the local lesion had subsided (160 and 275 days after the original inoculation). The rabbits were then reinoculated with the homologous strain of treponemes, both in the original cornea and also in the skin of the back.

The incidence of lesions developing in either cornea after reinoculation was higher than the incidence of lesions developing in the skin. The lesions developing in the corneas of the "immune" animals had a longer incubation period and were of shorter duration on the average than the lesions in the control group. No difference was noted in intensity of reaction.

Inoculation of the cornea of rabbits with syphilitic virus is often followed by the development of immunity to the homologous strain of organisms. This immunity is imparted to the skin to a greater extent than to either the cornea inoculated originally or the opposite uninoculated cornea. It persists after treatment with arsphenamine. It appears to be more marked the longer treatment is postponed.

In one half of all the test animals both cornea and skin were immune to a second inoculation of homologous syphilitic virus. In addition to these were five animals in which the cornea was immune and the skin nearly so. Thus in two thirds of the animals there developed a high degree of resistance

to reinoculation by a homologous strain of syphilitic virus following primary intracorneal inoculation.

Owen C. Dickson.

Chesney, A. M., and Woods, A. C. Further observations on the relation of the eye to immunity in experimental syphilis. 3. The influence of a non-specific inflammatory reaction in the cornea on the development of immunity in that tissue after intratesticular inoculation. *Jour. Exper. Med.*, 1944, v. 80, Nov. 1, p. 369.

Two experiments are reported in which rabbits originally inoculated with syphilis and treated late in the course of the disease (174th to 210th day) were reinoculated subsequently in both corneas with a homologous strain of syphilitic virus. In each animal one cornea was inoculated with dead tubercle bacilli prior to reinoculation with the syphilitic virus. This procedure was carried out in order to bring about a nonspecific inflammatory reaction with resultant vascularization, the intention being to find out if such vascularization would render the cornea more resistant to inoculation with the homologous strain of syphilitic virus. The results of both experiments were similar and while they were not conclusive, they indicated that there was a tendency for corneas which had been injected with dead tubercle bacilli to be more refractory to a subsequent inoculation with homologous syphilitic virus than the corneas of the same animals that had not been injected with dead tubercle bacilli. This tendency may be interpreted as suggestive evidence for the view that in the syphilitic rabbit there develop circulating antibodies toward the homologous strain of *T. pallidum*.

Friedenwald, J., and Buschke, W. The effects of excitement, of epinephrine, and of sympathectomy on the mitotic activity of the corneal epithelium in rats. *Amer. Jour. Physiology*, 1944, v. 141, July 1, p. 689.

Excitement or annoyance of rats, particularly by painful stimuli, diminishes the mitotic rate in their corneal epithelium. The decrease of mitotic rate caused by excitement is an adrenergic response and can be simulated by local or systemic application of epinephrine. Both ergotamine and nicotine diminish the mitosis inhibition following excitement. The effect of epinephrine is not due to a decrease in tissue temperature or to local disturbances.

Removal of the cervical ganglion leads to a decreased mitotic rate in the

rat's corneal epithelium after a lag period of twenty hours. It is suggested that this effect is attributable to absence of some factor, other than sympathin, which regulates mitotic activity in this tissue under physiologic conditions, and that this manifestation of denervation may be related to that of sensitization.

Theodore M. Shapira.

Galton, E. M. G. Treatment of perforating corneal ulcer. *The Lancet*, 1944, v. 247, Aug. 26, p. 272.

Within a period of six months 15 cases of perforated corneal ulcer were seen and treated. Most of the cases were seen four to eight days after perforation and prolapse. Only three of the cases were free of trachoma. The remainder were usually in stage 3 or 4 of the disease. Patients were prepared for two days before operation by irrigation with mild antiseptics, and those with heavy infections were given sulfanilamide by mouth and as a local application.

At operation visor or double-visor flaps were used and the prolapsed iris excised. Little difficulty was encountered in freeing the iris tissue with spatulas in spite of the time interval. Sulfanilamide or acriflavine was instilled, and both eyes were kept covered for four days.

In every case the corneal ulcer healed and there were no septic complications. In the two literate cases the visual result was good. Vision in the illiterates could not be tested.

Fralick, F. B. Rubeosis iridis diabetica. Amer. Jour. Ophth., 1945, v. 28, Feb., pp. 123-139. (One color plate, 17 photomicrographs, one table, references.)

Friedenwald, J. S. Dynamic factors in the formation and reabsorption of aqueous humor. Brit. Jour. Ophth., 1944, v. 28, Oct., pp. 503-510.

The problem of determining the factors responsible for the lack of complete equilibrium between blood and aqueous is approached by a detailed analysis of the secreting and re-absorbing mechanism of the eye. The articles by Kinsey, Grant, and Cogan (Amer. Jour. Ophth., 1942, v. 25, p. 760) and Duke-Elder and Davson (Amer. Jour. Ophth., 1944, v. 27, p. 307) on aqueous-humor dynamics are reviewed, and the author points out that his findings agree with those of Duke-Elder and his co-workers in regard to the constitution of the aqueous and with the findings of Kinsey and his co-workers in regard to the velocity of exchange between the blood and aqueous. (References.) Edna M. Reynolds.

Friedenwald, J. S., Hermann, H., and Moses, R. The distribution of certain oxidative enzymes in the ciliary body. Trans. Amer. Ophth. Soc., 1943, v. 41, pp. 141-156.

The authors have developed methods for isolation of the secretory portion of the ciliary body. They give details as

to dissection of the ciliary processes and removal of the epithelium. Techniques for identification of cytochrome oxidase in the epithelium and stroma are included. Cytochrome-oxidase activity was practically confined to the epithelium. The basal portion of the epithelium contained abundant cytochrome oxidase but was devoid of succinodehydrogenase. The authors therefore suggest that succinodehydrogenase is not part of the redox chain in the ciliary processes of the beef eye. (12 figures, 5 tables, references.)

Ravin, L. C. **Bilateral metastatic uveitis ending in phthisis bulbi as a complication of measles.** *Arch. of Ophth.*, 1944, v. 32, Oct., p. 301.

A three-year-old girl was seen following a severe episode of measles with associated bilateral otitis media and pneumonia. Sulfathiazole had been administered for three days prior to admission to the hospital. Examination revealed moderate lacrimation and photophobia with hyperemia of the conjunctivas. There was slight bilateral ciliary injection and turbidity of the aqueous. Complete annular posterior synechiae and pupillary membranes were present. Under atropine and sulfadiazine, the ciliary injection and photophobia gradually subsided. When examined five months after onset, each vitreous was a large pseudogliomatous mass through which the fundus could not be seen; and the globes were soft and moderately shrunken. There was no perception of light with either eye. (References.) John C. Long.

Sená, José A. **Sympathetic serous uveitis.** *Arch. de Oft. de Buenos Aires*, 1943, v. 18, Jan., p. 38.

The author reports two cases of the serous form of sympathetic ophthalmia which had a mild course and resulted in a complete cure under routine local treatment and the administration of mercury and neosalvarsan. The frequency of this form of sympathetic ophthalmia does not justify the bad prognosis usually applied to all cases of the disease. It is in the plastic form that the outlook is really dark. Aside from the importance of early diagnosis and institution of vigorous treatment, the mild course of serous sympathetic uveitis is due to lower virulence of the causal agent or a greater resistance of the individual. Preservation of the exciting eye in one of the cases leads the author to reaffirm his belief in prophylactic enucleation, but also to oppose therapeutic enucleation, except when

extensive involvement of the exciting eye threatens to make it painful or functionally useless. The literature on the subject is discussed, and a résumé of the cases of serous sympathetic ophthalmia published by Vogt is presented. (Photomicrographs, bibliography.)

8

GLAUCOMA AND OCULAR TENSION

Berens, C., and Nilson, E. Etiology of so-called chronic simple glaucoma. Possible role of focal infections, especially of the nasal accessory sinuses. Trans. Amer. Acad. of Ophth. and Otolaryng., 1944, 48th mtg., Jan.-Feb., pp. 121-148.

The ipsilateral relationship between chronic simple glaucoma and nasal pathology apparently observed in several patients led to detailed study of 53 unselected cases of simple glaucoma which showed various indications of sinus infection and nasal pathology. Of these, 37 (79 per cent) either had unilateral glaucoma or showed more signs of glaucoma in one eye than the other, nasal involvement being greater on the ipsilateral side. In six cases, the glaucoma was bilateral and the sinus involvement was the same on both sides. In ten cases, the glaucoma was worse on the side with the lesser nasal involvement. In no instance were the glaucoma and the nasal involvement both limited to one side. The nasal bacteriologic findings were inconclusive. Among the possible causative factors mentioned are vasomotor disturbances caused by chronic hyperplasia of the sinuses, venous stasis, and bacterial sensitization. Thorough investigation of the upper respiratory tract and appropriate treatment are advised in patients with chronic simple glaucoma.

In discussion, Alan Woods doubted the existence of any noteworthy relationship between chronic simple glaucoma and sinus disease or nasal infection. Generally speaking, glaucoma is not benefited by eradication of nasal infection or radical operations on the sinuses. Otolaryngologists do not encounter simple glaucoma more frequently in patients with sinus disease and nasal infection than in any other similar group of patients. (One table, 10 figures, references.)

Charles A. Bahn.

Kravitz, Daniel. Carbaminoylcholine chloride in the treatment of glaucoma. Arch. of Ophth., 1944, v. 32, Oct., pp. 283-286.

Carbaminoylcholine chloride is a sympathetic choline derivative which acts principally by inducing parasympathetic stimulation. Its action and chemical structure are similar to those of acetylcholine, but its effect is much more prolonged because of its slow rate of hydrolysis in the tissues. The absorption of carbaminoylcholine chloride is improved if the drug is prescribed in a wetting agent, such as zephiran, and if the eye is massaged through the lids after instillation. The drug has been of primary value in the treatment of chronic glaucoma, especially in cases which do not respond to pilocarpine or physostigmine. It is also useful as a replacement for miotics to which an intolerance has developed. Apparently a 0.75-percent solution of carbaminoylcholine chloride has slightly more effect than a 2-percent solution of pilocarpine nitrate and about the same effect as a 0.25-percent solution of physostigmine salicylate. The drug sometimes causes prolonged blurring of vision and occasionally pain.

The author reports the use of the drug in eight rather complicated cases of glaucoma. All types of glaucoma have responded to its use but good results have not been obtained in all cases. It is suggested that pilocarpine, physostigmine, mechoyl and neostigmine should first be tried and carbaminoylecholine chloride substituted if the previous response is not satisfactory. (References.) John C. Long.

Kronfeld, P. C., and McGarry, H. I. Results of surgical treatment of acute congestive glaucoma. *Quarterly Bull. Northwestern Univ. Med. School*, 1944, v. 18, no. 3, pp. 203-214.

The authors compare the results of various surgical procedures in use for the control of intraocular tension in acute congestive glaucoma. Iridectomy failed in 56, iris incarceration in 23, and corneoscleral trephining in 21 percent of cases. The remarkable failure of iridectomy was due to the presence of several-day-old, extensive, and unbreakable peripheral synechias, a view confirmed by clinical and gonioscopic observation. Iridectomy should, therefore, be used only in the very early stages of acute congestive glaucoma. Although both iris-inclusion and trephine operations were successful in a large number of cases, the best results in the hands of the writers were had, eight in succession, with basal iridectomy combined with small iris incarceration. A six-mm.-high conjunctival flap is made down to the limbus. After a scratch incision at the external scleral sulcus with a keratome (iridectomy ab externo) the prolapsed iris is excised by several small snips with the de Wecker scissors. In one corner of the wound, however, the iris prolapse is incarcerated by cutting the adjacent portion of the prolapse off its insertion

and crowding this portion of the iris into the angle of the wound. (3 tables, references.) R. Grunfeld.

RETINA AND VITREOUS

Esteban, Mario. Orientation for treatment of thrombosis of the retina. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, Jan.-Feb., pp. 106-114.

There are three aspects of thrombosis of the retinal veins upon which rational therapy is based. First, if a phlebitis is indicated, treatment should be directed toward the etiologic agent, syphilis, tuberculosis, or septic infection. For the latter the author considers the use of the sulfonamides of prime

importance, because by this means not only the primary focus is treated but also the local infection. Second, anticoagulants, such as heparin or leeches, should be resorted to early. Third, the slowed local circulation should be improved by local bleeding, as with leeches and massage.

J. Wesley McKinney.

Gans, J. A. **Classification of the arteriosclerotic-hypertensive fundus oculi in patients treated with sympathectomy.** *Arch. of Ophth.*, 1944, v. 32, Oct., pp. 267-275.

Eighteen hypertensive patients were treated by very extensive total or subtotal paravertebral sympathectomy including denervation of the retinal vessels by stellate ganglionectomy. The 15 patients that survived the operative procedure showed varying degrees of lowering of the blood pressure. A classification of fundus changes was devised to express separately the degree of arteriolar sclerosis and of acute hypertensive change. In the classification of arteriosclerosis, A 0 represented no sclerotic change in the fundi. Minimal signs of arteriolar sclerosis, such as widened arterial reflex, irregularity of lumen, and early crossing signs, were indicated as grade A 1. More advanced vascular changes were designated as grade A 2. Focal vascular insufficiency as evidenced by arterial closure or venous thrombosis with other signs of advanced vascular disease were graded as A 3. Absence of any acute hypertensive change was indicated as H 0. Edema of the nerve fibers, blurring of the disc, or preorganic vessel spasm was represented as H 1. The presence of hemorrhage or soft exudate was indicated as H 2, while measurable papillary elevation was designated as H 3. The fundi of 11 of the patients were

classified according to the A and H designations.

Fundus observations confirmed the beneficial effects of sympathectomy. Following the operations there was disappearance of hemorrhages, exudates, and papilledema. In the majority of cases, however, sympathectomy did not do away with vessel spasm and neural edema. The best results were obtained in patients with the least retinal arteriolar sclerosis. John C. Long.

Gradle, H. S., and Sugar, H. S. **Self-limitation of retinal separations.** *Quarterly Bull. Northwestern Univ. Med. School*, 1944, v. 18, no. 3, pp. 174-183.

Nine cases of traumatic separation of the retina are described. In every case the lower portion of the retina was involved and in every case there was noted between the normal and separated retina a line of demarcation consisting of either diffusely pigmented chorioretinal scars or of retinal stripes, white lines bordered by pigment. The self-limitation must be considered as a favorable end result in untreated cases of traumatic retinal separation, and thus the prognosis is not entirely hopeless for those cases in which early operation is excluded on account of extensive hemorrhage into the vitreous. (One table, 10 figures, references.)

R. Grunfeld.

Hine, M. L. **The end results of operation for detachment of the retina (with a follow-up of fifty successful cases).** *Brit. Jour. Ophth.*, 1944, v. 28, Nov., pp. 575-585.

A full analysis of 120 cases of retinal detachment is given. Of this group, 50 cases were successful. All except five of these cases were followed for a year or more. Twenty of the cases had

secondary operations, three of which were successful. Thirteen cases had had previous detachment in the other eye. Four cases were aphakic and none of these was successful.

Myopic cases numbered 49. Of these, 17 were successful. Multiple holes were present in 18 cases. Of these 6 were successful. In 6 cases no hole or disinsertion could be found, but 4 of these eyes were aphakic. One of these cases was successfully operated upon. Age, in itself, does not determine the prognosis. There were an equal number of successful operations under 40 and over 40 years. The detachment of longest standing which was successfully operated upon was in a boy aged 13 years who had suffered an injury over two years previous to operation. The position of the retinal tear has no bearing on the success of the operation. The author stresses the importance of careful, repeated examination and carefully planned operative procedure. (One illustration.) Edna M. Reynolds.

Lawson, Arnold. *Scientific and clinical aspects of night vision*. Trans. Ophth. Soc. United Kingdom, 1943, v. 63, pp. 61-64.

The author takes up the physiologic basis of night vision, and some special problems related to night vision at sea. Experimentally, in a collaborated study with Russ, he tried to ascertain whether acuity of vision in dim light was related to variations in transparency of the eye to shortwave radiations within the range of normal vision. It was found that all nocturnal animals examined had a very marked transparency to radiations which were not at all transmitted through the human eye. In the human eye there seems to be a very considerable absorption of radiations within the range of normal

vision. It is definitely known that scotopic vision is carried out by the retinal rods, also that in nocturnal animals there are very few cones. The owl, which showed the greatest transparency of all the animals tested to short-wave radiations, hunts entirely by sight and without the aid of scent.

At the beginning of the war, men with good night vision for lookout work at sea were difficult to find, but the use of any adaptometer which secured a satisfactory estimate of the light threshold in the simplest and shortest way was of great help. The use of binoculars at night always tends to produce eyestrain, and the men often work in pairs so as to rest their eyes frequently. (One figure.)

Beulah Cushman.

Lijó Pavía, J. *Diathermic surgery of the retina*. Rev. Oto-Neuro-Oft., 1944, v. 19, July-Aug.-Sept., pp. 97-109.

In his cases of noninflammatory retinal detachment the author records a rather high percentage of satisfactory results—85 percent, if treated within two months of the onset. The major part of this paper deals with diathermic treatment of other retinal and choroidal conditions which predispose the eye to or cause detachment of the retina. Intraocular tumors, exclusive of choroidal cyst and iris melanoma, have responded to coagulation diathermy, with atrophy of the tumor and satisfactory retinal adhesions. One case of Coats's exudative retinitis responded to diathermy, with good cicatrization and the retention of some vision. Several cases of angiomatosis retinae have been helped.

The essay includes an excellent series of panoramic retinographs illustrative of one of the cases treated. Lijó Pavía argues that diathermy should no

longer be confined to cases of retinal detachment, but should be used also in the treatment of certain intraocular tumors, and in Hippel's and Coats's diseases.

Edward Saskin.

Livingston, P. C. **Scientific and clinical aspects of night vision.** Trans. Ophth. Soc. United Kingdom, 1943, v. 63, pp. 51-60.

The author describes the methods used to investigate the loss of rod sensitivity in anoxia acquired at the equivalent of 18,000 ft. altitude. Topics considered include aspects of the subject beyond the boundaries of physiology, and the two properties associated with scotopic vision which make its study significant; and use of a function of the retina in measuring a dysfunction of the body; and range of the perceptive power of the eye when daylight has gone. Night visual capacity embraces all associated reactions.

Another phase concerns the stages of night which can be divided into zones of cone-rod effectiveness. There is the sharp macular vision of cone derivation or nautical twilight, when cone and rod vision are balanced at an illumination in the region of 0.002 foot candles. This corresponds with that period of twilight when visual judgment is apt to become faulty. Beyond this stage, rod function predominates and visual processes become more settled. Further problems discussed involve scotopic examination of the central visual field. This showed characteristic features: (a) general enlargement of the blind spot with greater detail of contour; (b) a central scotoma; (c) a scotomatous area in the extreme upper field in 20 percent of the cases; (d) the presence of an area of heightened rod sensitivity in the form of a circle around the fixation point; (e) contraction of

the field if the luminosity of the test object was sufficiently reduced. Finally investigations showed that the rods were less resistant to oxygen deficiency than the cones. (5 figures, references.)

Beulah Cushman.

Marburg, Otto. **The endocrine glands in infantile amaurotic family idiocy.** Jour. Nervous and Mental Dis., 1944, v. 100, Nov., p. 450.

Tissue studies were made in three cases. The most striking change in the endocrine glands was a lack of adrenal medulla. Changes in the other glands were also noted. The work of numerous other investigators in this problem is referred to and discussed.

F. M. Crage.

Moreu, Angel. **Reflections on the problem of hemeralopic retinosis.** Arch. de la Soc. Oft. Hisp.-Amer., 1944, v. 4, Jan.-Feb., pp. 115-130.

This is an attempt to explain the basic pathology of hemeralopic retinosis (retinitis pigmentosa). From clinical and experimental studies which are cited the author postulates that the primary lesion (degeneration, infections, toxic, and so on) is located in the hypothalamus. (12 diagrams.)

J. Wesley McKinney.

Parsons, John. **Scientific and clinical aspects of night vision.** Trans. Ophth. Soc. United Kingdom, 1943, v. 63, pp. 64-66.

The author emphasizes the care necessary in regard to the adaptation curve, as threshold values should be measured under similar and comparable conditions. The physicist and physiologist are at variance as to the particular range where both rods and cones function. In the problem of night flying, moonlight gives a rod-and-cone

combination, but the transition from moonlight to starlight results in a practically complete scotopic condition in which vision is very bad. From the point of view of practical tests for flying and for conditions in darkness there must be fundamentally a reasonably good dark-adaptation curve, but superimposed on that there is a highly complex state of affairs in which form vision and intelligence are involved with a host of other things.

Beulah Cushman.

Pickard, Ransom. **Scientific and clinical aspects of night vision.** Trans. Ophth. Soc. United Kingdom, 1943, v. 63, pp. 68-69.

The author speaks of the need for adoption of a standard area of stimulation, and an instrument to provide for estimation of an adaptation curve, the final result being given as light value for a given area. Beulah Cushman.

Pollak, H. **Some metabolic and nutritional factors affecting dark adaptation in peptic-ulcer patients.** Trans. Ophth. Soc. United Kingdom, 1943, v. 63, pp. 69-74.

More recent observations have shown little correlation between the photometric readings and vitamin-A intake with impairment of dark adaptation, but a much closer relation to some metabolic inefficiency due to ill health. Dark adaptation on the whole may be the index of liver function rather than of vitamin-A intake.

The author's study of dark adaptation in patients with peptic ulcer showed that the degree of abnormality bore some relation to deterioration in general condition. He feels that failure in dark adaptation can not be explained by inadequate vitamin-A intake but rather by hepatic dysfunction and dis-

turbances in vegetative control. Therapy to improve liver function was used in the form of ascorbic acid, aneurin, nicotinic acid, and other factors of the vitamin-B complex in yeast and liver extract; and with it there were indications of a trend toward normality of dark adaptation. (One figure, references.) Beulah Cushman.

Riddell, W. J. B. **Scientific and clinical aspects of night vision.** Trans. Ophth. Soc. United Kingdom, 1943, v. 63, pp. 43-50.

The author states that night vision involves the whole visual pathway from the corneal epithelium to the visual cortex, also that the psychology of the person to be examined and that of the examiner must be taken into account.

All tests must reckon with the intensity and duration of the light, the size of the test-patch area of the retina stimulated, the color of the light, and the duration of the exposure. A standard exposure of the patient before the test is also necessary.

Most patients who complain of difficulty in dull light have no objective symptoms, but anxiety states can usually be placed first as etiologic factors, followed in order of importance by visible pathologic retinal changes, errors of refraction, hereditary night blindness, hysteria, and dietary deficiency. (2 figures, references.)

Beulah Cushman.

Robertson, G. W., and Yudkin, J. **Studies in dark adaptation as a means of detecting deficiency of vitamin A.** Brit. Jour. Ophth., 1944, v. 28, Nov., pp. 556-568.

Studies of dark adaptation of various groups (1,500 subjects) as a means of detecting deficiency of vitamin A are reported. Because of the effects of age

on dark adaptation; the results are presented in three parts. First, groups of children from 9 to 12 years are compared; then, groups of young adults from 15 to 22 years; lastly, subjects over 22 years.

Children from three Cambridge schools were compared with children in a village school. The diet of the children in the village school might have been expected to be higher in vitamin A than that of the children in the city schools, but the children in the village school showed significantly poorer dark adaptation than the children in the Cambridge schools. Although the Cambridge school children represented various economic levels, they showed no appreciable difference in dark adaptation.

The group of young adults was made up of men and women college students and nurses and Birmingham factory workers. The nurses and college students were equally good in dark adaptation and all were better than the two groups of factory workers.

The older group of subjects was made up of Cambridge nurses and Sheffield workers. These were compared with the Birmingham factory workers. The dark adaptation of the Sheffield workers was about the same as that of the Birmingham workers, while that of the nurses was better than either group of factory workers.

A group of 14 laboratory workers received supplements of vitamin A (24,000 I.N.) or half a pound of carrots (about 20,000 I.N. carotene) daily. Six of these showed definite improvement in dark adaptation after a three weeks interval.

Birmingham factory workers who received a daily supplement of 5,000 I.N. vitamin A, 1 mg. vitamin B₁, 25 mg. vitamin C, and 500 I.N. vitamin D for

a period of eight months showed a significant improvement in dark adaptation, while the group which did not take the vitamin supplement showed no appreciable alteration in dark adaptation. Vitamin supplements given at three of the Cambridge schools produced no alteration in dark adaptation. (3 tables, 4 figures, references.)

Edna M. Reynolds.

Rosen, Emanuel. Photographs of retinal detachment in aphakia, before and after operation. *Brit. Jour. Ophth.*, 1944, v. 28, Nov., pp. 554-556.

Rosen reports a case of successful operation for retinal detachment in an aphakic eye in a patient aged 61 years with a mild grade of diabetes associated with marked hypertension. The vision in the operated eye with correction has remained at 20/25 for three years. (2 fundus photographs, 2 visual-field charts.) Edna M. Reynolds.

Wright, W. D. Scientific and clinical aspects of night vision. *Trans. Ophth. Soc. United Kingdom*, 1943, v. 63, pp. 66-67.

The author advocates that greater attention be paid to the phenomena which occur after cessation of preadaptation, which may be the most exciting part of the adaptation curve. Some observers show recovery of sensitivity immediately when light adaptation ceases, while in others there may be a delay of twenty seconds before any recovery is recorded. The explanation of adaptation phenomena in terms merely of visual-purple regeneration is not adequate. Measurements on the luminosity curve at various intensity levels indicate, from persistence of the Purkinje shift, that the rods continue to function at high levels of illumination.

Beulah Cushman.

13

EYEBALL AND ORBIT

Brain, W. R. Thyrotoxicosis in relation to ophthalmology. Trans. Ophth. Soc. United Kingdom, 1943, v. 63, pp. 3-8.

The author considers the significance of the three main symptoms in thyrotoxicosis: exophthalmos, lid changes, and ophthalmoplegia. He describes the clinical syndromes in which these may be combined, and some lines of surgical and medicinal treatment. (2 tables, references.)

Beulah Cushman.

Jackson, Harvey. Thyrotoxicosis in relation to ophthalmology. Trans. Ophth. Soc. United Kingdom, 1943, v. 63, pp. 39-40.

The author makes a plea for diagnostic caution in cases of unilateral exophthalmos, as in his experience several cases labeled as of thyrotoxic origin were proved finally to depend upon orbital tumor. The use of X rays and visual fields may be of great help with the general findings of thyrotoxicosis.

Beulah Cushman.

Moffatt, P. McG. Thyrotoxicosis in relation to ophthalmology. Trans. Ophth. Soc. United Kingdom, 1943, v. 63, pp. 19-21.

Six days after admission to the hos-

pital of a woman of 45 years with bilateral exophthalmos, a transfrontal decompression of the right orbit was done, as the right exposed cornea was in good condition. The cornea cleared during the operation, and the proptosis was reduced considerably. Bilateral tarsorrhaphy was done, but the adhesions broke down within 12 days and the left eye had to be eviscerated.

Tarsorrhaphy was repeated on the right lids nine days later, but again broke down by the end of the week. Six doses of deep X-ray therapy were given to the pituitary gland, but caused severe headache. Ulceration of the lower third of the right cornea did not improve. Iodine therapy had no effect. Partial thyroidectomy was performed six weeks later and the patient made a good recovery, but the eye remained the same. One month later the ulcer seemed safe and the patient went home. She began to develop attacks of depression and delusions of persecution.

Two months later, further measures seemed necessary to keep the eye safe, and a decompression of the lateral walls of the orbit was done. Following this there was further reduction in the proptosis and chemosis and the corneal ulcer healed. The final vision was 6/18. The author concludes that transfrontal decompression of the orbit and other procedures should be done as soon as it is realized that minor measures are not sufficient. (One photograph.)

Beulah Cushman.

Mulvaney, J. H. Thyrotoxicosis in relation to ophthalmology. Trans. Ophth. Soc. United Kingdom, 1943, v. 63, pp. 22-38.

For the differentiation of exophthalmos the author presents the following classification as a working basis: (1) the hyperthyroid complex to include

thyrotrophic hyperthyroidism depending on pituitary control, of which familiar examples are found in the last third of pregnancy or in acromegaly; (2) thyrotoxicosis (Graves's or Basedow's disease and exophthalmic goiter), a compound expression of hyperthyroidism and sympathicotonia apparently maintained independently of thyrotrophic stimulation; (3) thyropathic hyperthyroidism, a result of abnormal structural alterations in the thyroid gland usually transient in nature and exemplified in certain instances of early neoplasm, lymphadenoid goiter, and inflammation.

Mulvaney feels that the proptotic mechanism is a forward traction on the globe induced by spasm of the anterior orbital unstriated musculature acting in the presence of weakened voluntary extraocular muscles. These include the upper and lower palpebral muscles of Müller and the circular muscle of Landström. The weakness of voluntary muscles is probably due to thyrotoxic myasthenia and to suppression or excessive destruction of acetylcholine at the myoneural junction, and to atonia from local neuromuscular degeneration. The pathologic changes in the muscles vary according to the different types, each of which the author analyzes at length. (8 illustrations, references.)

Beulah Cushman.

Savin, L. H. Thyrotoxicosis in relation to ophthalmology. *Trans. Ophth. Soc. United Kingdom*, 1943, v. 63, pp. 9-18.

Many patients with early thyrotoxicosis may come first to the eye physician with complex symptoms of asthenopia out of proportion to the ocular findings, the symptoms resembling an anxiety neurosis, and all symptoms being exaggerated by any emotional dis-

turbance. An abrupt manner, dilated pupils, slightly widened palpebral fissures upon excitement may make one suspicious of thyrotoxicosis.

Efficient premedication should be used before any operative procedure, and the eyes should be protected with vaseline pads at all times. Complete tarsorrhaphy should be done early, combined if necessary with lateral tarsorrhaphy for persistent mild degree of exophthalmos. (2 figures, 2 tables, references.)

Wright, R. E. Plastic spheres for implantation into Tenon's capsule in the Frost-Lang-type operation for enucleation of the eyeball. *Brit. Jour. Ophth.*, 1944, v. 28, Nov., pp. 573-574.

Methyl-methacrylate-resin spheres perforated in two diameters at right angles and fluted on the surface in a basket-work pattern are recommended as implants following enucleation of the eyeball. The spheres are anchored by catgut sutures to the superior and inferior recti through the vertical tunnel and to the lateral and medial recti through the horizontal tunnel. The sutures are tied over the top of the globe. The fluting of the globe is intended to supplement the fibrous tissue anchorage which eventually takes place. (3 illustrations.)

EYELIDS AND LACRIMAL APPARATUS

Beiras García, Antonio. Contribution to the surgery of the lacrimal passages—"lacrhorhinoplasty." *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, Jan.-Feb., pp. 26-32.

The operation proposed, and carried out in three cases, is as follows: The skin is incised as for dacryocystorhi-

nostomy. The tear sac is extirpated, if present. A large opening is made into the nose, preserving the nasal mucosa. A vertical incision is made in the nasal mucosa forming a large anterior flap and short posterior flap. The internal canthus is retracted nasalward with a two-pronged hook. Using a large keratome, a curved vertical incision is made immediately behind the caruncle, with its concavity backward, and the incision is carried into the lacrimal fossa between the two branches of the internal palpebral ligament. The posterior flap of nasal mucosa is sutured directly to the conjunctiva if this can be accomplished without too much tension. If not, a graft of buccal mucous membrane 8 to 9 mm. wide is interposed. The anterior flap of the nasal mucosa is sutured to the anterior lip of the conjunctival wound. Here again, if there is too much tension a buccal-mucous-membrane graft is interposed. Thus, two epithelial surfaces face each other. The ligament is sutured and the skin incision closed. The operation is completed by inserting in the new-formed canal a metallic cylinder 5 mm. in diameter and 14 mm. long. One of the posterior conjunctival-graft sutures is left long and tied through a hole in the ocular end of the metal tube to hold it in place. The posterior lip of the ocular end of the tube is bent forward to prevent its rubbing the globe. The tube is removed in eight to ten days. In two of the three cases reported a permanently patent passage resulted. (3 figures.)

J. Wesley McKinney.

Belmonte González, Nicolás. **Lacrorhinostomy.** Arch. de la Soc. Oft. Hisp.-Amer., 1944, v. 4, Jan.-Feb., pp. 33-36.

A tubular tunnel is made between the lacus lacrimalis and the nose, and is

lined anteriorly with a flap of conjunctiva and posteriorly with a flap of nasal mucosa. In two of the three cases reported, the tunnel became completely closed. In the third, the result was described as only partially successful. (2 color plates.) J. Wesley McKinney.

Lorente Buesa, Marcelo. **Hemorrhage in dacryocystorhinostomy, its prophylaxis and treatment.** Arch. de la Soc. Oft. Hisp.-Amer., 1944, v. 4, Jan.-Feb., pp. 48-58.

The principal and most feared complication of dacryocystorhinostomy is hemorrhage. No case should be operated upon unless the coagulation and bleeding time are normal. The bony opening should be made as high and as far forward as possible in order to avoid the ethmoid cells and the erectile tissue of the middle turbinate. No part of the nasal mucosa should be left without sutures. Effective postoperative care is very difficult in the presence of severe hemorrhage.

J. Wesley McKinney.

Marín Amat, Manuel. **Problems which dacryocystorhinostomy poses.** Arch. de la Soc. Oft. Hisp.-Amer., 1944, v. 4, Jan.-Feb., pp. 37-47.

In the author's opinion secondary hemorrhage is the complication of dacryocystorhinostomy most to be feared. It arises principally from the vertically coursing blood vessels, which are cut by the horizontal incisions used in making the flaps of nasal mucous membrane. The author discusses this incision and he questions its wisdom. Three cases of failure of the operation are recorded, all of which were reoperated. In each case return of epiphora was due to closure of the nasal opening by adherence of the posterior flap to the anterior. The operation of Ar-

ruga for reestablishing drainage into the nose after extirpation of the tear sac is described, and the author's technique of dacryocystorhinostomy is given. (10 figures.)

TUMORS

Basterra, Jesús. Cholesteatoma of the orbit. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, Jan.-Feb., pp. 66-71.

There had been considerable erosion of the roof of the orbit. At operation the cholesteatomatous mass was found between the periorbita and the bone. There was no apparent capsule. It is postulated that the condition is due to embryonic rests of ectodermal origin. (4 figures, references.)

J. Wesley McKinney.

Costi, Carlos. Recurrent glioma treated by the radiotherapy of Chaoul. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, Jan.-Feb., pp. 72-74.

Local recurrence of glioma was treated with 8000 R. in fractional doses. The tumor disappeared completely, only to return within three months.

J. Wesley McKinney.

Cumings, J. N., and Sorsby, A. Unilateral and bilateral retinoblastoma—a possible histological difference. *Brit. Jour. Ophth.*, 1944, v. 28, Nov., pp. 533-537.

Histologic studies of 19 cases of retinoblastoma from the Royal Eye Hospital are reported. Eight of the tumors were unilateral, eight bilateral, and three hereditary. The unilateral tumors all showed fairly solid arrangement of cells, except one which tended to grow in a papillomatous manner. Little fibrous-tissue stroma was to be seen,

but blood vessels were fairly prominent. Necrosis was common, with polymorphonuclear infiltration. The cells composing the tumor were small, with the nucleus almost filling the cell. Mitoses were not very common. In each case it was possible to make out the passage from normal retina to tumor. This change took place gradually in most cases, and the tumor could be seen arising from the outer nuclear layer, with portions of the inner nuclear layer covering the tumor and gradually thinning out until it disappeared entirely. Three of the cases had multiple tumor-nodules.

The bilateral tumors showed the same general arrangement of cells, which tended to be somewhat larger and to contain more cytoplasm. Mitoses were no more common than in the unilateral tumors. Some of the tumors were multiple, as in the unilateral group, but, in contrast with the unilateral cases, all the bilateral tumors appeared to arise either from the inner nuclear layer only or from both nuclear layers. In no case did the tumor originate from the outer nuclear layer only.

The familial tumors resembled the bilateral type microscopically. Neuroglial fibers were not found in any of the tumors, and in only one case was reticulin demonstrated. In this case, it appeared to be derived from the wall of the orbit. The three hereditary tumors were bilateral and did not appear to differ from the sporadic bilateral type. (One table, 4 figures.)

SYSTEMIC DISEASES AND PARASITES

Fornes Peris, Enrique. Histopathology of an eye affected with cysticercus. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1944, v. 4, Jan.-Feb., pp. 98-105.

This is a complete pathologic report on an eye enucleated because of continued painful endophthalmitis. Electrocoagulation had been done two years previously in an attempt to destroy a cysticercus in the vitreous. All the structures of the eye with the exception of the cornea and sclera showed evidence of chronic inflammation. In the anterior vitreous was a large mass to which the lens and detached retina were adherent, and which microscopically resembled granulation tissue infiltrated with lymphocytes and polynuclears. In front of this mass was the cellular cysticercus, larval form of *tenia solium*, with the characteristic hooks of the cestode. The cysticercus had evidently been dead for some time, as it was infiltrated with calcium. But it could not be determined whether the cysticercus had died as a result of the electrocoagulation or from strangulation by the reactional mass. (4 photomicrographs, references.)

Dr. Thomas F. Wickliffe, Jasper, Alabama, died November 26, 1944, aged 64 years.

MISCELLANEOUS

Emory University has postponed the ophthalmologic seminar, which had been scheduled for April 19th to 21st, on advice from the War Committee on Conventions.

The next examination by the American Orthoptic Council will be held in September-October, 1945.

The written examinations will be held at various cities in the country on Friday, September 7, 1945. Only those passing the written examinations will be permitted to take the oral and practical tests, to be given in Chicago, Saturday, October 6, 1945.

Applications on official forms must be received before July 1, 1945.

Address the American Orthoptic Council, 23 East 79th Street, New York 21, New York.

The nineteenth semi-annual Wood's course in refraction will be held by Drs. Ralph H. Woods and Aubrey H. Pember and associates, April 29th to May 4th, inclusive, at Pember-Nazum Clinic, Janesville, Wisconsin. The fee is \$75.00. Registration is limited. For further information please address Dr. A. H. Pember,

500 W. Milwaukee Street, Janesville, Wisconsin.

SOCIETIES

At the February dinner meeting of the Cleveland Ophthalmological Club the guest speaker was Dr. A. D. Prangen of the Mayo Clinic, who spoke on "Some aspects of refraction." Dr. L. V. Johnson, Cleveland, gave a review of his work on ocular toxoplasmosis.

At the meeting of the Washington, D.C., Ophthalmological Society, held on March 5, 1945, the guest speaker was Col. Derrick Vail (MC), who spoke on "War ophthalmology." Dr. Benjamin Rones reported a case of "Anomalous vascular loop in the macula." The following case presentations were made: "Juvenile disciform degeneration of the macula" by Dr. Joseph Dessoff; "Foreign body puncturing soft tissues of the orbit and extending into the brain" by Dr. Thomas Rees; "Anterior capsular cataract due to trauma" by Dr. Frank D. Costenbader; and "Corneal striae" by Dr. Benjamin Rones.

At its meeting on January 17, 1945, the Reading Eye, Ear, Nose, and Throat Society sponsored the organization of the Diplomates' Association of Physicians of Berks County. All diplomates of Boards, listed in the Directory of Medical Specialists, have been invited to join. A joint meeting with the Reading Eye, Ear, Nose, and Throat Society will be held once a year. At this first joint meeting, Dr. Harrison F. Flippin of Philadelphia spoke on "The clinical use of penicillin."

PERSONALS

Col. Derrick Vail has been appointed Professor of Ophthalmology and Head of the Department at Northwestern University, and will assume the duties on his release from the Army. Colonel Vail's present address (correction of the notice in the March issue) is:

Col. Derrick T. Vail (MC) 0491780

Office of the Surgeon General
Room 507 C

1818 H St. N.W., Washington 25, D.C.

Lt. Col. M. E. Randolph, formerly Chief, Branch of Ophthalmology, Surgical Consultants Division, Surgeon General's Office, has been assigned to Valley Forge General Hospital as Chief of the E.E.N.T. Division. He replaces Lt. Col. James N. Greear, who has recently sailed overseas, assigned as Senior Consultant in Ophthalmology to the Chief Surgeon, European Theater of Operations.

Superior Quality CONTACT LENSES

The expert care and skill of your examination and prescription is carried through to completion when you prescribe "Obrig" Contact Lens. You are assured of exact and careful attention to every detail in your prescription.

Obrig Contact Lenses assure your patients the same careful attention in detail and accuracy as that exercised in your examinations.

Obrig's contributions in the manufacture and fitting of Contact Lenses has eliminated guess work and increased wearing time.

When prescribing Obrig Contact Lenses our expert consultants and facilities are at your service.

*Pontocaine
Hydrochloride*

in

OPHTHALMOLOGY

and in

RHINOLARYNGOLOGY

*Surface Anesthetic
with Prolonged Effects*

Dependable anesthesia
of the mucous membranes

is readily obtained by the topical application of Pontocaine hydrochloride. This widely used agent acts quickly, penetrates deeply, and gives prolonged anesthesia. A variety of operative and nonoperative procedures on the eye, nose and throat may be successfully carried out with small quantities of relatively weak solutions.

HOW SUPPLIED: For surface anesthesia in ophthalmology: 0.5 per cent solution in bottles of ½ oz. and 2 oz.

For surface anesthesia in rhinolaryngology: 2 per cent solution in bottles of 1 oz. and 4 oz.

DIRECT UTILIZATION OF THE EYE AS A CAMERA*

WILLIAM A. MANN, M.D.

Chicago

(With the collaboration of RALPH CREER, CAPT., U.S.A., formerly of the Department of Clinical Photography, U. S. Veterans' Hospital, Hines, Illinois)

It is generally recognized that Christopher Scheiner, the Jesuit philosopher, was the first to demonstrate the actual formation of an inverted image upon the retina by making a window at the posterior pole of the eye. Although the date of this experiment is generally given as 1619,¹ (the date of publication of his "*Oculus hoc est*," according to Von Rohr, who has translated Scheiner's works from Latin into German) Scheiner did not report this actual demonstration upon the eyes of animals until publication of his "*Rosa Ursina*" in 1925.^{2,3} Scheiner's original monographs were unobtainable by the essayist for verification.

The camera obscura had been invented long before Scheiner's investigations and has been credited to Giambattista della Porta (1545-1615), although Leonardo da Vinci and Don Pronince⁴ may have antedated Porta, and Polyak finds evidence that its principle was known to the ancient Greeks.⁵ In spite of the obvious comparison of the eye to the camera obscura there was considerable reluctance, both before and after Scheiner's momentous contribution, to accept as a fact the inversion of the retinal image, a premise

which had first been evolved upon theoretical grounds by Kepler in 1611.⁶

Prior to Joannes Kepler's monumental contributions as a pioneer in physiologic optics there had been no clear idea of the mechanism of the formation of the retinal image, and, in fact, little advance from the early Galenic hypothesis of the lens as the receptor of visual impulses. Following the publication of Scheiner's classic experiment numerous investigators corroborated his findings, which have become, especially when performed with an albinotic eye, a standard laboratory demonstration in physiologic optics. In 1638 Rene Descartes removed the posterior wall of the eye and replaced the retina with the flat surface of another object, upon which the image was observed.⁵

Finally in 1877, Kühne,⁷ in carrying out extensive studies on visual purple, produced his famous "optograms," which led to the popular fallacy (still persisting) of the face of the murderer being observed on the retina of the victim. What Kühne did accomplish was to produce an image on the retina by prolonged exposure, light causing a change in the rhodopsin which could be observed grossly for a short time. Using albinotic rabbits, eyes of birds, or, in some cases, eyes with a thin sclera and only moderate choroidal pigmentation, he brought the

image (usually a flame, but in some cases a large photographic negative held against the sky) to a focus on the retina as exactly as possible by observation of the sclera (as a ground glass) at the posterior pole of the eye. The animal had first been dark-adapted for 15 minutes, decapitated, and the eye enucleated under a sodium light. After exposure, the duration of which he varied but which usually was for several hours, the eyes were placed in 4 percent aluminum potassium-sulfate solution for 24 hours in the dark. The purpose of the alum solution was to make the subsequent removal and inversion of the retina more readily accomplished and *did not serve to fix the image*, as had been widely misquoted but emphatically denied by the author himself. He was not successful in "fixing" the image chemically in a photographic sense, but after the retina was inverted by punching out the optic nerve and removing the retina under water, he could observe the optogram in the floated retina for as long as 30 minutes and if the retina were then dried in a desiccator the image persisted for a much longer period. The image of the flame was well reproduced, but more complicated subjects, such as the photograph of a man, did not show details well.

In 1926 Hidano⁸ photographed for the first time the image formed by the eye. He constructed an apparatus consisting primarily of a metal tube 35 mm. in diameter with a circular opening in the base 12 mm. in diameter. Into this the freshly enucleated eye of a dog was placed with the cornea protruding through the opening. Plaster of Paris was placed around the eye to hold it in position and a large window was made at the posterior pole of the eye, by removing the sclera, choroid, and retina. Behind the eye was a closed chamber with a piece of glass at the back and an ingenious device connected with a mercury manometer by

which the intraocular pressure could be controlled through use of Ringer's solution in the chamber. The cornea was also protected by a chamber containing Ringer's solution. He found that if the tension were not controlled the globe would collapse and if the cornea were not protected it would become clouded. By using a mirror at a 45-degree angle behind the apparatus and a photographic camera in the proper position, the image formed by the eye was reflected by the mirror into the camera, and it was possible to obtain quite clear photographs with a resulting magnification of about three times. These photographs gave no information as to the refraction of the eye, as a clear picture could be obtained whether the image was formed in the vitreous, the normal position of the retina, or even behind the globe. In a subsequent experiment⁹ he inserted a screen in the normal position of the retina, photographing the image on the screen with various lenses placed in front of the eye. A thin layer of paraffin was placed between two cover glasses to form this screen, which was arranged so that it could be moved forward or backward by means of a screw. This screen meant that, departing from the method of his first experiments, he was now photographing the image approximately as it would be formed *on the retina*.

Lashley¹⁰ in 1932, photographed the image in albino rats' eyes, the sclera of the undissected eye being used as a screen upon which the image was formed. The eyes were kept in a moist chamber throughout the experiment, and it was found that good transparency could be maintained for as long as 30 minutes.

Since the invention and development of the modern camera, with its almost universal use throughout the civilized world and the wide understanding of its general principles, the comparison between

the photographic camera and the eye has naturally and repeatedly been made, especially when attempting to describe the function of the eye to the general public.¹¹ Verbitzky⁴ has even calibrated the relative apertures of the schematic eye in terms of photographic lenses as $f/6$, $f/4$, and $f/12$ for pupils of 4 mm., 6 mm., and 2 mm., respectively.

In spite of this frequent comparison of the eye to a modern photographic camera and the retina to the sensitized emulsion on the photographic plate or film, a thorough study of the literature does not reveal any evidence that any investigator has ever attempted to *substitute* such film for the retina and thus actually utilize the eye as a camera. While Hidano, Lashley, and possibly others have photographed the retinal image as previously described, they made use of a camera for that purpose and in no case registered the image on sensitized photographic emulsion placed within the eye itself.

In contemplating the possibilities of direct utilization of the eye as a camera certain difficulties are at once suggested. It is self-evident that all media must remain as transparent as possible. Post-mortem changes are especially apt to cause corneal clouding, particularly if the epithelium becomes dry for too long a period of time. Reduction of intraocular pressure incidental to opening the globe may further contribute to loss of transparency. These factors Hidano felt it necessary to overcome to maintain ocular transparency, and to that end he constructed the somewhat complicated apparatus already described. Eyes should be used as soon after enucleation as possible, and if any appreciable time interval elapses it would seem desirable that precautions be used to keep the tissues as well preserved as possible to avoid more than minimal post-mortem changes. Since the globe must be opened posteriorly to

admit the photographic film (which because of its pliability would seem more suitable than a plate) every effort must be made to prevent vitreous loss, and some method would have to be employed to assure that the film was placed in the proper position, comparable to that normally occupied by the retina. Since the image will be small (not enlarged by the process of photography as in Hidano's experiments) it is desirable to utilize a very fine-grain photographic emulsion. Mees¹² has emphasized the fact that since the photographic image consists of grains, no matter how sharp the edge of the theoretical image which produced it may be, it will appear more or less ragged under high magnification. The resolving power of an emulsion is the product of three factors—graininess, turbidity, and contrast—giving a very complex reaction. Therefore, no matter how fine-grained an emulsion is used, it is not to be expected that it will be possible to obtain too clear a positive print if one attempts to enlarge a negative with an image in any way approaching the small size of the macular image. It is consequently to be expected that an area much larger than the macula must be utilized.

With these difficulties anticipated, an attempt was made to substitute photographic film for the retina in the eyes of various animals, and to obtain on that film photographic images by utilizing the eye as a camera. In the series of experiments conducted, the eyes of pigs, sheep, beeves, cats, and rabbits were employed. The first three were obtained fresh from the Chicago stockyards, the latter two were from laboratory animals, the eyes being enucleated just prior to the experimental procedures. It was found that sheep's eyes were the most satisfactory for this work; they approximate the human eye anatomically (although they are larger in all dimensions, averaging 28 mm. in length),

the media remain clear, and the vitreous is not so fluid as that of rabbits or cats. Beef eyes were too large for satisfactory comparison to the human eye, and pigs' corneas tend to become clouded, for the animals are sprayed with an anti-septic solution before being slaughtered, in accordance with U. S. Government reg-

Fig. 1 (Mann). Apparatus for holding eye. Shows outer tube mounted in stand (center); inner cup for eye with optical glass in back (lower right); and metal cap (lower left).

ulations. All eyes from the stockyards were used as soon as possible, but there was of necessity an interval of several hours between the time of their removal and their use in the laboratory. Immediately upon receipt from the slaughterhouse they were placed, wrapped as delivered, in a refrigerator with the temperature set at 5°C. With these precautions the media remained grossly quite clear and a very clear view of the fundus could be obtained with the ophthalmoscope.

The first attempts to obtain a photographic image were made by simply placing a strip of unexposed film in front of the retina. Two parallel incisions, about 4 mm. long and about 3 mm. on either side of the estimated position of the macula, were made through the sclera, choroid, and retina. Working in the dark with only a photographic safety lamp, the

writer placed a strip of film 4 mm. wide through one incision, across in front of the retina, and out the other incision. The film was then pressed forward slightly on the lateral side of each incision to make it fit snugly against the retina and conform to its curvature. This was accomplished without appreciable loss of vitreous. The whole posterior segment of the eye was then covered with a dark cloth to eliminate extraneous light and an attempt was made to photograph a visual-acuity chart about 17 feet away, using a flashlight bulb. A very fast film, Super XX, was employed. In spite of repeated attempts along this line and the use of various exposure times, no image was obtained on the film. Only a black spot was recorded, showing that the portion of the film within the eye had been exposed to light.

It was realized that in this crude original effort no attempt had been made to get the image into focus and that if the eye were other than perfectly emmetropic with relaxed accommodation in this post-mortem state one could not hope for a clear retinal (or photographic) image, without the use of a ground glass for focusing.

With the assistance of Mr. Hunter of the Belgard-Spero Optical Company, a metal container was constructed to hold the eye (fig. 1). This consisted of a piece of brass tubing 26 mm. long and 46 mm. in diameter, the front end open and the back end containing an opening in the brass 23 mm. in diameter, into which was cemented a piece of very thin optical glass, curved as nearly as possible to the posterior conformity of the globe. This inner cup for holding the eye was fitted snugly into a slightly larger piece of brass tubing with an open front and a circular opening in the back 28 mm. in diameter, and mounted on a standard to insure

steadiness and ease of handling. A metal cap was made to fit over the back of the outer brass cylinder into which could be placed a metal ring with a central opening, in case it was desired to place the film in position and protect it before being exposed. In practice, however, this cap and ring were not used, as no time was lost between getting the image into focus and then photographing it. Over the front

position of the macula, by the use of a cataract knife and sharp scissors to remove the window of sclera, choroid, and retina. It was found possible to do this without appreciable loss of vitreous or noticeable collapse of the globe. Holding the eye with the window up, the inner brass tubing was placed over it, so that the window was snugly against the optical glass at the back. The eye was held in this

Fig. 2 (Mann). Sheep's eye mounted and held by plaster in inner cup, which has been assembled into outer tube. Note set screw at side for keeping position of inner cup firm. Eye ready for use as a camera.

Fig. 3 (Mann). View from rear of holder containing sheep's eye, showing window in coats of eye at posterior pole. Sclera fits firmly against optical glass.

of the outer cylinder could be placed a camera shutter to assist in regulating the time of exposure and if desired, narrowing the size of the effective pupil, which in these animals was usually quite dilated. Such a shutter was used in a number of the experiments performed but, in general, proved to be of no great advantage, all exposures being instantaneous. For other types of objects photographed it might, however, offer an advantage.

In preparing the eye for photography, it was first necessary to dissect from the sclera all adherent fat and connective tissue, then a small square window, approximately 4 mm. in size, was cut at the posterior pole of the eye in the estimated

position while the whole was inverted. In order to hold the eye in the proper position with the window against the optical glass and not permit any loss of vitreous, a quick-setting plaster (Kerr's Snow White Impression Plaster No. 2) was poured around the eye from in front. This held it securely, and it was not found that the plaster reached the posterior part in any way to interfere with visualization through the glass and window. Dental cement (S. S. White) was also tried for this purpose; it held the globe securely but became so hard it was difficult to remove, hence its use is not recommended. The inner tube was then mounted in the outer holder, being pushed completely to the

back of it, so that the center of the optical glass protruded slightly through the opening in the outer cylinder (figs. 2 and 3). During this process of preparation the media usually remained quite clear, and with an ophthalmoscope one could read newspaper print placed against the optical glass. In some cases the cornea was irrigated with normal saline solution at short intervals.

A part of a visual acuity chart had been photographed on a negative which was

Fig. 4 (Mann). Instantaneous exposure of visual-acuity-chart negative with transmitted light.

Fig. 5 (Mann). Newspaper headline with daylight and 1/50 second exposure.

Fig. 6 (Mann). Human eye, 60-watt bulb, and 1/10 second exposure.

placed on the front of an ordinary viewing box, giving a constant illumination from behind, with the letters appearing white against a black background. When the eye in its holding apparatus was directed toward this object the letters from this chart were seen sharply and distinctly as inverted letters in the window at the back of the eye. It was noted, however, that this was true for any and all distances at which the eye might be placed from the chart. This was due to the fact that the image was clearly seen by the observer's eye whether it was formed in the vitreous, in the retina, or in the air behind the window. This was demonstrated by placing a small piece of ground glass against the optical glass. When this was done the letters were visualized on the ground glass *only* when very exact focusing was done by varying the distance of the eye from the object, a very slight increase or de-

crease of this proper distance for focusing then causing the image to blur and disappear entirely. Many films were exposed with negative results before the need of such precise focusing was realized in practice, although it had been anticipated on a theoretical basis. The extremely sharp image seen in the window had been deceptive; thereafter all focusing of the image was done with the ground glass. It was found in all cases that for a sharp focus on the ground glass the distance from the object to the eye must be rather close, as might in part be accounted for from the fact that these animal eyes often showed a slight degree of myopia when viewed with the ophthalmoscope, this being further increased by the fact that the film was of necessity placed slightly behind the normal position of the retina, with the thickness of the choroid, sclera, and optical glass lying in front of the film. Post-mortem changes together with lowered intraocular pressure might also be a factor in exaggerating the apparent myopia.

When this apparatus was used, as indicated above, with a small piece of film backed with black photographic paper held over the optical glass behind the window, satisfactory photographic images were obtained of the visual-acuity chart and several other objects as indicated in the illustrations (figs. 4 to 12). Exposure time could not be measured exactly except in a few cases in which the shutter was employed; in the majority the exposure was instantaneous, the light in the viewing box being snapped rapidly on and off. After the proper position of the eye had been determined by use of the ground glass the film was placed in position in the dark by the sense of touch and exposed and immediately developed.

Every effort was made to keep the cornea clear by keeping it moistened with

Fig. 8 (Mann). This is figure 5 enlarged about five times.

Fig. 9 (Mann). This is figure enlarged about six times.

Fig. 7 (Mann). This is figure 4 enlarged about seven times.

normal saline, and fresh eyes were used after every few exposures. However, in one case a satisfactory photograph was made after an eye had been kept overnight in an icebox. In some cases, when the eye appeared to be abnormally soft, normal salt solution was injected into the vitreous with a hypodermic syringe, to produce an approximately normal ocular tension. No other effort was made to maintain the intraocular pressure at a normal range, but especially when sheep's eyes were used the eyes did not appear to develop sufficient hypotension to produce effects deleterious to the object of the experiment.

While the practical importance of utilizing the eye for a camera and obtaining an image which approximately corresponds to the image cast on the retina of the eye in life may not be overwhelming, it does suggest possibilities in physiologic optics, at least in a demonstration of well-

known hypotheses. For example, the size of the retinal image in relation to the object and the distance could be well demonstrated, especially with further improvements in technique. Our difficulty in this regard, in spite of repeated attempts, lies in the extremely small size of the retinal image when the object is at any distance, making photography of distant objects almost impossible. Accepting the hypothesis that the smallest resolvable retinal image must have a diameter just greater than a macular cone (about 0.002 mm. according to Schultze¹³) we must conclude that present photographic emulsions would not permit photographing an image approaching the minimum visual angle. For practical purposes this is considered to be about one minute, although on theoretical grounds it would be less. Adler¹⁴ has called attention to some of the factors that may influence the visual acuity, such as errors of refraction, size of

the pupil, intensity of illumination, and use of monochromatic light (experimental). He has also called attention to other factors, such as the aligning power of the retina, which is much more sensitive than the resolving power and which, together with physiologic influences, may greatly increase the visual acuity. In determining standards of visual acuity, the minimal visual angle of 60 seconds has been generally accepted, however, as the normal. In photographing retinal images we can, of course, eliminate all physiologic factors, but we must substitute those of a

where AB is the object, ab the image, and N the nodal point of the eye:

$$\begin{aligned} ab:AB &= bN:BN \\ ab &= AB \times bN/BN \\ \text{Since } bN &= 17.054 \text{ mm.} \\ i &= 17.05 \times O/D \end{aligned}$$

where O is the size of the object and D its distance from the nodal point of the eye.

Since the length of the eye will not always conform to the measurements of the schematic eye the image will be slightly larger in an axially myopic eye

Fig. 10.

Fig. 11

Fig. 12.

Fig. 10 (Mann). This is a photograph obtained with a rabbit's eye, enlarged about four times.

Figs. 11 and 12 (Mann). These are higher magnifications of images obtained with sheep's eyes.

physical or mechanical nature, especially as related to the nature of the photographic emulsion.

The size of the retinal image is dependent upon the visual angle formed by the object and not upon the distance of the object from the eye, so long as the distance is within the limits of accommodation, as emphasized by Southall.¹⁵ Although there is a theoretical difference in the size of an image from an object subtending 1 degree at the anterior principal point of the eye from the state of full relaxation of accommodation to greatest accommodative effort, this shows a difference in size of the image between 0.293 mm. during relaxation and 0.286 mm. during accommodation, and may therefore be disregarded.

The simplest formula for determining the theoretical size of the retinal image is quoted by Duke-Elder¹ as follows,

and smaller in an axially hyperopic eye.

Attempts to prove these relative image sizes were not too successful with the sheep's eye and this photographic method. For example, in a sheep's eye—which required a —18.00D. lens in the ophthalmoscope to visualize clearly newspaper print held against the optical glass, with the eye placed as described in the holder, indicating an effective myopia of —18.00D.—it was found that the image was brought to a focus on the ground glass when the eye was placed 5.5 cm. from the object to be photographed. When a —13.00D. lens was placed 1 cm. in front of the cornea, the distance from the object to the cornea required to obtain a sharp focus was increased to 18.7 cm., findings quite consistent with the degree of myopia as estimated. Satisfactory exposures of the film were made at these distances. Measurement of the "O"

in the "TOZ" on the developed film at the 18.7-cm. distance from object to cornea showed it to measure 0.9398 mm. in its greatest horizontal meridian. Estimating the distance from the object to the nodal point of the eye as 198 mm., and measuring the actual horizontal diameter of the "O" in the object photographed to be 13.43 mm., should, according to the formula for estimating image size, give a resultant image of 1.1873 mm. (instead of the actual 0.9398 mm.). Several other estimations at other distances gave a similar discrepancy with about the same proportionately small size of the actual image that could be theoretically deduced.

As an explanation of this apparent error it should be emphasized that the formula used for computing the image size is based upon the findings for the *human* eye with a nodal point 17.05 mm. in front of the retina. The sheep's eye, being somewhat longer (average 28 mm.) and having a different corneal curvature, will naturally have a different nodal point, the distance of which in front of the retina has apparently never been calibrated. If one could assume the accuracy of the conditions under which the image was formed and photographed to be comparable to that existing in the living eye, it might be possible to deduce from the known formula for image size the position of the nodal point in the sheep's eye. In order that the image formed should measure 0.9398 mm. in the foregoing experiment, with the distance to the cornea 187 mm. (and therefore 215 mm. from the object to the retina or film) one would have to assume that the nodal point was approximately 14 mm. in front of the retina. This is proved by the formula:

$$i = N \times O/D$$

$$i = 14 \times \frac{13.46}{201} \text{ or } 0.9353$$

It does not seem reasonable to assume that the nodal point in any eye 28 mm. long lies as far back as 14 mm. in front of the retina and no such claim is made. It would seem probable that the technical difficulties involved together with post-mortem and ocular-tension changes and the myopia noted account for the apparent error.

Further discrepancies occurred when the eyes used for photography were placed at any great distances from the object which were incompatible with the degree of refractive error estimated. For example, in one eye with an estimated 18 diopters of myopia (to the film, not to the normal position of the retina) a focus was obtained when the cornea was 5.5 cm. from the object, as would be expected. With a -7.50D. sph. placed 2.5 cm. in front of the cornea the distance was 6.5 mm., and with a -13.00D. sph. the distance increased to only 11 cm.; with a -17.00D. sph. to 12.5 cm., and with a -20.00D. to only 20 cm. The image became so minute at this distance that it was impossible to carry the experiment further.

It is realized that the images in all these experiments are not macular images only, due to the very obvious impossibility of photographing such minute images by present methods. Further objections may be made to the fact that the position of the film was slightly behind the normal position of the retina. Since no claim is made that the images formed are any indication of the vision obtained by the animal in life (as no consideration is given to the function of the higher visual centers) the fact that much more than the fovea is involved in the formation of these images is not really a valid criticism. The main object has been to demonstrate that the eye can actually be used as a camera, a fact that is of interest chiefly because of the frequent comparison made

between the two. It is conceivable that with future developments in photography it may be possible to demonstrate mathematically the size of retinal images according to the accepted formulas, and perhaps to prove experimentally other theories in physiologic optics.

No human eyes were available for this

study, but there is no reason to expect any important facts to be demonstrated by their use which cannot be brought out with these animal eyes, with the possible exception of more accurate determination of image size.

THE USE OF ARTIFICIAL-FEVER THERAPY IN OPHTHALMOLOGY

IVAN C. SMITH, MAJOR (MC), A.U.S., AND GILBERT C. STRUBLE,
LT. COL. (MC), A.U.S.

While fever-producing agents are commonly and effectively used by ophthalmologists, the use of so-called artificial or mechanical methods of fever production have not been commonly employed in this field. The most frequently used agents have been triple typhoid vaccine, sterile-milk injections, and similar agents. It is our belief that artificial or mechanical fever has been neglected in many cases when its use might have been more effective than the agent employed.

Most objections which have been raised to the use of artificial fever we believe have been based on unsound grounds. Many of these accounts are based on reports of techniques which were in use before the artificial methods of production were developed to their present degree. Also some are based on the technique used in the treatment of sulfanamide-resistant gonorrhea, which requires prolonged sessions of high fever and is not comparable to the techniques usually employed in treating ocular diseases. Some of the objections frequently made to the use of mechanical methods will be mentioned and evaluated in an effort to correct the impressions which we believe to be in error.

1. It is thought by some that other methods possess a nonspecific action which operates even when no fever is produced. This theory has been advanced since the early days of malarial therapy, but no conclusive proof that it is true has ever been introduced. In most instances it is noted that therapeutic results obtained are usually in direct relation to the height of the febrile reaction.

2. Another objection frequently heard is that the mechanical treatment is too strenuous. Most of our treatments were

not over two hours in length, given at a therapeutic elevation of not over 105°F. and frequently less. The total elevation time was not over 3½ to 4 hours. When it is remembered that with artificial-fever therapy there is no preliminary chill, with its attendant malaise and headaches, it is obvious that it is actually less strenuous than fever therapy induced by triple typhoid vaccine. Some patients (other than eye) who have received both triple typhoid vaccine and 8-hour sessions of fever above 106°F., have stated to us that they prefer the latter method, their chief objection to typhoid vaccine therapy being the chill.

3. Another contention is that artificial fever is more dangerous. There have been many more deaths and serious complications reported from the use of foreign protein and vaccines than from artificial means. While it is true that many more such treatments have been given, the incidence of serious complications in mechanical fever is probably not proportionate. Most serious accidents encountered in artificial therapy have been in the cases treated with long high fevers. Another safety factor is that the mechanical methods require expert care by trained technicians, and there is no danger that they will be carelessly given. The same facts may be used to answer another objection raised; namely, that more nursing care is needed when treatment with mechanical fever is employed. Certainly a patient with a temperature of 105°F. needs just as much care regardless of the cause of the fever. If a patient is to be given an injection of typhoid vaccine in the office and sent home, the nursing care is not given but the risk is increased. If it is given in the hospital the problem of nursing care is

just as great. It is probably much safer to give a short session of mechanical fever in the morning and to allow the patient to return to his home that evening.

4. The expense factor is frequently mentioned. While this will vary in different localities, it will be equalized in most cases if the patients are hospitalized for their vaccine therapy and treated on an ambulatory basis with mechanical means. This is practicable because the mechanical method is controllable and can be completed in a few hours, leaving the average patient in the same condition as before the treatments. In military practice, there is no difference, for the patients are hospitalized in both instances.

The unavailability of mechanical-fever therapy is the most justifiable objection. However, it has been neglected even where it is available in favor of other methods, probably because more practitioners are familiar with the other methods. If mechanical fever is popularized, there is no reason to believe it will not be made generally available.

Mechanical methods of producing fever do have certain disadvantages. Once a patient is started on malaria therapy or has received an injection of vaccine or foreign protein, he cannot decide to discontinue the treatment. There are several ways in which he can cause the mechanical treatment to be discontinued, as his coöperation is necessary to the successful administration of the treatment. He may not keep all his appointments for mechanical-fever sessions.

In our opinion, however, the advantages of mechanical-fever therapy far outweigh the disadvantages, one of the greatest advantages being that temperatures of any duration and height are easily obtained, and that if necessary

they may be repeated on the following day.

Drug therapy need not be discontinued during fever. In the series of cases herein presented, it will be noted that in most instances mechanical fever has been employed with chemotherapy in the form of either sulfadiazine or penicillin.

The Eye Department at this general hospital finds that Army and Navy personnel react erratically to the intravenous injection of triple typhoid vaccine. It is believed that this is a result of their routine immunization to typhoid and paratyphoid organisms. In rare instances these patients appear to have developed a sensitization to the vaccine and will develop unduly high temperatures. One such patient developed a temperature elevation of 106°F. for four hours following the intravenous injection of 25 million killed organisms. In most cases, however, the febrile reaction leaves much to be desired. In our experience the temperature elevation rarely is greater than 100.6° and frequently not over 99.6°F., following the first injection (25 million killed organisms).

Another objection to the use of triple typhoid vaccine in some instances is the fact that it cannot safely be used on two successive days. This is due to the possible occurrence of a second reaction on the day following its injection.

This fact together with the uncertainty of the febrile reaction places the attending ophthalmologist at a serious disadvantage. Prompt, adequate, and repeated fever therapy is a sight-saving measure in many eye diseases. This is particularly true of the following conditions:

1. Beginning intraocular infection following penetrating injuries.
2. In acute optic neuritis or retrobulbar neuritis of inflammatory origin.

It is not unusual in such cases for vision to drop from normal to light perception in only a few hours' time. Recovery following adequate fever therapy is frequently just as spectacular.

3. In acute secondary glaucoma due to blockage of the iris angle with inflammatory debris. Particularly is this true of those cases in which repeated paracentesis and other means have been unsuccessful in controlling the tension.

4. In acute iridocyclitis.

5. In cases of severe corneal ulcer and corneal abscess. Space does not permit a résumé of all of the many types of ocular pathologic change which respond favorably to fever therapy. These have been well covered in many previous reports by competent observers. Cordes¹ has made a comprehensive report of this subject together with a very complete bibliography.

The following cases treated by artificial-fever therapy at Billings General Hospital are reported. This group does not constitute all the ophthalmologic cases treated by this method. A variety of different pathologic conditions is presented to show the possibilities of mechanical-fever therapy. It will be noted that a number of cases are included which had been treated previously with triple typhoid vaccine with unsatisfactory results. To date, no complications whatever have been encountered.

CASE REPORTS

CASE 1. DISCIFORM MACULAR DEGENERATION (KUHN JUNIUS TYPE). E. R. H., aged 35 years was admitted to the Eye Service, Billings General Hospital, on February 21, 1944, complaining of blurred vision in the right eye of three weeks' duration.

Vision on admission was: O.D. 20/20 -2, J1 blurred (uncorrectable), ma-

crospia present, and O.S. 20/20.

The eye examination was negative except for the following fundus changes in the right eye: There was a slaty-gray oval elevated lesion one-half disc diameter in size at the temporal margin of the fovea. This was elevated one-half diopter. Hemorrhage in the deep layers of the retina was noted along the temporal margin of the lesion and there was some subretinal infiltration, with hemorrhage extending below and nasally to the fovea. A 4-degree absolute paracentral scotoma was present.

A diagnosis of Kuhn Junius macular degeneration of the juvenile type, right eye, was made. The patient was thoroughly studied. The throat, sinuses, and prostate were negative. Dental consultation and full mouth X-ray studies revealed an advanced degree of periodontal infection, for which a complete extraction was ordered. Blood studies including the serologic tests for syphilis and agglutination tests for undulant fever were negative. The Frei test was negative. X-ray studies of the chest and medical consultation failed to demonstrate any evidence of pulmonary disease. Intradermal skin tests, using old tuberculin in the dilution 1 to 10 million, were strongly positive. Because of the nature of the pathologic change in this type of lesion (hemorrhage beneath Bruch's membrane)² it was felt some form of therapy should be used which might cause the absorption of this bleeding. In view of the patient's extreme sensitivity to tuberculin, the close proximity of the lesion to the fovea, and the fear of a focal reaction following tuberculin therapy, with the likelihood of permanent loss of central vision, it was decided to withhold tuberculin therapy until fever therapy could be given a trial.

The first fever treatment was given on

March 1st. Therapeutic time 2 hours; temperature elevation 105°F. , total elevation time 4 hours, 15 minutes. Penicillin (100,000 units dissolved in normal saline) was administered intravenously during the therapy. Examination of the fundus oculi the following day showed no evidence of exacerbation of the lesion, and absorption of a large part of the deep retinal hemorrhage. Four more fever treatments were administered.

March 6th. Therapeutic time 4 hours; elevation time 5 hours, 35 minutes. Temperature elevation to 105°F. , with simultaneous administration of 100,000 units of penicillin, by intravenous injection.

March 9th. Therapeutic time 3 hours; elevation time 4 hours, 50 minutes. Temperature elevation to 105°F. ; 100,000 units of penicillin were given by intravenous administration during the treatment.

March 13th. Therapeutic time 3 hours; elevation time 5 hours, 10 minutes. Temperature elevation to 105°F. ; penicillin, 100,000 units, administered by intravenous injection.

March 16th. Therapeutic time 3 hours; elevation time 5 hours, 15 minutes. Temperature elevation to 105°F. ; penicillin, 100,000 units, administered by intravenous administration.

During the period of treatment all evidence of active bleeding at the margins of the lesion had disappeared. The lesion itself had become flattened and much less conspicuous. After the first fever treatment on March 1st, removal of the diseased teeth was begun. Extractions were followed by ophthalmoscopic study to be on the alert for any evidence of focal eye reaction. No such reaction occurred and the elimination of all dental foci was accomplished without incident. Vision on March 24th was holding at 20/20-2, and the patient was discharged to duty after dental prostheses had been fitted. He has been followed at intervals in the

Eye Out-Patient Department since. The vision remains 20/20-2 and there has been no evidence of reactivation of the macular disease.

We believe that fever therapy arrested the progress of the macular lesion in this case. It is of further interest that improvement in the fundus picture began after the first treatment and prior to the removal of the dental sepsis. The cleaning up of the dental infection following fever therapy may have played a role in maintaining arrest of the lesion.

CASE 2. CHRONIC RECURRENT SUPERFICIAL PUNCTATE KERATITIS WITH SECONDARY IRIDOCYCLITIS. E. H. L., a colored officer, aged 26 years, was admitted to the Eye Service, Billings General Hospital, on May 30, 1944, for treatment of a bilateral chronic recurrent keratitis and iridocyclitis of eight months' duration.

Vision on admission was: O.D. 20/200, J1, correctable to 20/20-2 with -3.00D. sph. O.S. 20/100, J1, correctable to 20/25-1 with -3.00D. sph.

Pertinent findings at this Hospital were those of a bilateral recurrent superficial punctate keratitis, with some associated photophobia and blepharospasm due to secondary iritis. The conjunctiva showed only a moderate hyperemia, and repeated smears and cultures of conjunctival scrapings were negative. Both eyes showed numerous 1-by-1-mm. round, healed, corneal opacities, most marked at the limbus, and a few scattered similar opacities in the center of the cornea of the left eye. This patient had been thoroughly studied during his eight months of continuous hospitalization prior to admission here.

Repeated serologic tests for syphilis were negative. One tooth, R-14, had been extracted because of a periapical abscess. Allergy study had shown nothing sig-

nificant except a strongly positive patch test to tuberculin. Desensitization to tuberculin had been carried out for the preceding $2\frac{1}{2}$ months, the patient having received 40 injections up to the time of his transfer to Billings General Hospital. Penicillin therapy, 15,000 units each injection, had been given by intramuscular injection over a 5-week period at 3-hour intervals day and night with only questionable benefit.

Fever therapy using typhoid vaccine had been unsatisfactory. Seven treatments in all had been given, the fever response to the first injection was 101°F. , to the second 100°F. , and to the next five injections the temperature elevation had varied from 99 to 99.6° . Biopsy specimen from a cervical gland with guinea-pig injection had been negative in 1941. Local treatment had consisted of the administration of atropine and hot compresses locally, a high-caloric and high-vitamin diet, with addition of riboflavin.

Following the patient's admission here, he was again carefully surveyed. X-ray studies of the chest, sinuses, and teeth were negative. The prostate gland was normal. Local treatment was continued; namely, atropine and hot compresses. Various local antiseptics, zinc sulphate, and metaphen brought about no improvement. Penicillin as local eye drops made up in normal saline (1 c.c. per 1,000 units, 3 drops) was given every hour during the day and every 2 hours at night for 2 weeks without benefit. General measures consisted of a high-caloric, high-vitamin diet with riboflavin and fortified with 75,000 units of vitamin A daily. Tuberculin desensitization was continued.

In spite of this therapy, however, the multiple areas of superficial punctate keratitis continued to recur in crops of 5 to 7 at a time. These would take a stain with fluorescein for 4 to 5 days and then

gradually heal, leaving no permanent opacity. On slitlamp study they appeared to involve only the outer half of the corneal epithelium. They were apparently less severe than the previous lesions, which had left permanent corneal opacities.

A prominent and consistent finding in this case had been an almost complete bilateral corneal anesthesia. Because of this fact, it was felt the disease might be largely on a neurotrophic basis. Because nothing else seemed to be offering this patient relief of his symptoms, it was decided to try fever therapy in the fever cabinet. The treatments were given as follows:

August 7th. Therapeutic time 2 hours, at 105°F. ; elevation time 3 hours, 15 minutes. *August 10th.* Therapeutic time 2 hours, at 105.6°F. ; elevation time 3 hours, 10 minutes.

A striking feature of the local ocular reaction to fever in this case was the prompt return of corneal sensitivity. This was noted the day following the first treatment and has been maintained. At the present writing, September 26th, both eyes have been free from the recurrent keratitis for over five weeks. Both eyes remain white and quiet and the patient has no symptoms referable to either eye.

CASE 3. GLAUCOMA, SECONDARY, CHRONIC. E. E. H., aged 37 years, was admitted to Billings General Hospital on January 28, 1944, complaining of intermittent pain over the left frontal and temporal regions, and blindness, pain, and redness of the left eye. The vision in the left eye had failed 12 years before. The right eye had no significant symptoms. The left eye showed an injected globe with a steamy cornea, a deep anterior chamber, seclusion and occlusion of the pupil, and an ocular tension of

60 mm. Hg (Schjötz). The left eye was also divergent about 20 degrees. Slitlamp examination showed no evidence of active iridocyclitis. Enucleation of the blind painful eye was advised but was refused, and the patient expressed a desire that some other surgical procedure be tried first in an effort to save the globe. A cyclodiathermy operation was performed on February 4th, three rows of diathermy-needle punctures being made over an area of two thirds of the ciliary body. At the same time the divergent strabismus was corrected by a tenotomy of the externus and a resection and advancement of the internus.

The postoperative reaction subsided slowly; on February 12th the tension had dropped to 43 mm. Hg. Fever therapy was advised in an effort to speed recovery and was given as follows:

February 15th. Therapeutic time 2 hours, 1 minute, at 103.3°F.; elevation time 3 hours. *February 21st.* Therapeutic time 3 hours, 15 minutes, at 103.5°F.; elevation time 4 hours, 45 minutes. *February 23d.* Therapeutic time 2 hours, at 103.3°F.; elevation time 2 hours, 30 minutes. *February 28th.* Therapeutic time 2 hours, at 103.3°F.; elevation time 3 hours, 30 minutes. *March 4th.* Therapeutic time 3 hours, at 105.3°F.; elevation time 5 hours, 5 minutes. *March 8th.* Therapeutic time 3 hours, at 105°F.; elevation time 5 hours, 15 minutes. *March 13th.* Therapeutic time 3 hours, 10 minutes, at 105.4°F.; elevation time 4 hours, 40 minutes. *March 16th.* Therapeutic time 3 hours, 5 minutes, at 105°F.; elevation time 4 hours, 30 minutes.

During this course of fever therapy the tension of the eye had gradually dropped to normal [13 mm. Hg (Schjötz) on March 17th] and the globe had become white. This patient noted so much relief of pain and congestion of the eye following the first fever therapy that he

asked that the treatment be continued. He was discharged to duty with a cosmetically good, quiet eye, and complete relief of the headaches.

It is our belief that fever therapy in this case hastened absorption of the postoperative reaction in the globe, materially increasing the patient's comfort and speeding his convalescence.

CASE 4. IRIDOCYCLITIS BILATERAL WITH CENTRAL EXUDATIVE CHOROIDITIS. R. E. C. was admitted to Billings General Hospital on November 1, 1943, for treatment of a recurrent gonorrheal urethritis. He had had three courses of sulfathiazole at previous hospitals but no permanent cure of his urethritis had resulted. He was treated with penicillin, 50,000 units divided into five 10,000-unit doses and given at 3-hour intervals. Following this therapy, he developed a clinical cure and was discharged on November 16th, but the urethritis again recurred and the patient was again hospitalized on December 7th, at which time he was given 100,000 units of penicillin divided into 10 doses given at 3-hour intervals. This therapy effectively cured the urethritis and the patient was discharged on December 13, 1943. On December 30th, he was admitted to the Eye Service, Billings General Hospital, for treatment of an acute iridocyclitis of the left eye. Vision on admission was O.D. and O.S. 20/20, vision in the left eye being a little blurred. All foci of infection were eliminated. Repeated examinations of the prostate were negative for evidence of recurrence of his gonorrhea. The tonsils were removed. A full-mouth X-ray study showed periapical abscess of L-7 and 8, and these teeth were extracted. The blood serology was negative. Local eye treatments consisted of the administration of atropine and hot compresses. Foreign-protein therapy was instituted, using triple

typhoid vaccine beginning with 50 million killed organisms. These injections were continued for the next 5 weeks (until January 15th), being given at 3- to 4-day intervals and up to 300,000,000 killed organisms per injection. The febrile reaction was poor, the highest temperature attained being 100.2°F. Systemic reaction was severe and characterized by severe chills, headache, and depression. In spite of these measures, the iridocyclitis of the left eye had become worse, and vitreous opacities and macular edema had appeared in the left eye, with a drop in vision to 20/70, J3, uncorrectable. An active, acute iridocyclitis had also developed in the right eye. On February 1, 1944, 100,000 units of penicillin dissolved in 1,000 c.c. of normal saline were given by continuous intravenous drip, and on the following two days 100,000 units of penicillin were administered daily by intramuscular injection every 3 hours day and night.

On February 4th, the day penicillin therapy was stopped, the vision in the left eye had improved from 20/70 to 20/30, and the cells had almost disappeared from the anterior chamber and retro-lental spaces of both eyes. One week later the vision in this eye had slipped to 20/40—4 with recurrence of cells in both eyes. Good pupillary dilations and hot compresses had been maintained during this period. On February 8th, treatment with penicillin as local eye drops was begun (1 c.c. per 2,500 units, made up in normal saline). These drops were given every 2 hours day and night for 2 days, but no improvement in the macular picture or in the vision of the left eye ensued. There was, however, some clearing of cells in the anterior chamber of each eye following this therapy.

On February 10th, the patient was given his first treatment in the fever cabinet. Total therapeutic time 2 hours, 45 min-

utes at 106°F.; total elevated time 4 hours, 20 minutes. Penicillin (100,000 units) was administered by intravenous injection during this fever therapy. Visual improvement the following day was striking, the recorded vision on that day, February 11th, being 20/20 both eyes (uncorrected) as compared to 20/70 O.S. the day before. Only a few cells were present in the anterior chamber of either eye, and there was much less edema in the macula of the left eye. This patient received two more treatments in the fever cabinet: On February 16th, therapeutic time, 4 hours at 106°F.; elevation time 6 hours (100,000 units of penicillin were again given intravenously during the treatment). The vision remained 20/20 O.U. with both eyes white and with only an occasional cell in either anterior chamber until March 10th, at which time the vision of the right eye had dropped to 20/25—1 and the iridocyclitis had recurred in this eye. During the foregoing period, the patient had developed a marked local and general sensitivity to atropine. Hyoscine had been substituted, but after one week had to be stopped because of a generalized urticaria. On March 14th, he received his third treatment in the fever cabinet (therapeutic time 3 hours, 30 minutes at 106°F., elevation time 5 hours, 30 minutes) and 100,000 units of penicillin were again given intravenously during the fever treatment. On the following day, all cells had practically disappeared and the eyes remained quiet with uncorrected vision of 20/20, J1 thereafter. This patient was kept under observation for six more weeks, but there was no further evidence of recurrence.

This case presents many points of interest. We believe it probable that the etiologic factor was a sulfathiazole- and penicillin-resistant gonorrhea. The condition continued to progress with involve-

ment of the second eye in spite of fever therapy, with triple typhoid vaccine, the elimination of foci of infection, and local eye treatments. Temporary improvement of the anterior and posterior uveitis followed the intravenous and intramuscular injections of penicillin, but the condition recurred when penicillin was stopped. Some improvement of the anterior-segment disease was noted following the use of penicillin as local eye drops, but the macular lesion was not improved. Cure of the disease was rapid and permanent following the administration of adequate fever therapy in the fever cabinet. The simultaneous administration of penicillin with the fever therapy was probably of some benefit also.

CASE 5. CORNEAL ULCER. F. S., white male, aged 25 years, was admitted to the Eye Service of Billings General Hospital on July 17, 1944, because of severe pain, photophobia, and blurring of vision in the right eye of four days' duration.

Similar symptoms had been noted about two months before, and the patient had received treatment for a corneal ulcer for a period of six weeks elsewhere. There was no history of injury. Vision on admission was as follows:

O.D. 6/200, J7, correctable to 16/200, J6, with $-1.75D.$ sph. $\approx +.50D.$ cyl. ax. 120° ; O.S. 17/200, J1, correctable to 20/20, J1, with $-1.25D.$ sph. $\approx +.25D.$ cyl. ax. 60° .

The left eye was normal. The right eye showed an active deep corneal ulcer, 3 by 3 mm. in size, located 4 mm. from the limbus at the 7-o'clock position. It extended throughout the entire thickness of the cornea. Slitlamp study showed the surrounding cornea to be infiltrated over an area of about 5 mm. A very severe secondary iritis was present, with marked blepharospasm and lid edema. Scrapings from the corneal lesion showed many

white blood cells and an occasional gram-positive coccus. Treatment was instituted as follows:

1. Atropine 2 percent—2 drops in the O.D. every 3 hours.
2. Hot wet compresses to the O.D. 20 minutes every 2 hours.
3. Penicillin in normal saline (1 c.c.—5,000 units), 3 drops in the right eye every hour during the day and every 2 hours at night.
4. Penicillin in normal saline (1 c.c.—2,500 units) as local eye baths to the right eye for a period of 1 hour morning and evening. (The contact eye cup was used for this purpose.)
5. Complete survey for foci of infection.

By July 24th, the ulcer took no further stain with fluorescein, and the eye was much more comfortable; however, it remained red and photophobic and some lid edema persisted. The corneal infiltration surrounding the ulcer had cleared, but the original deep ulcer, on slitlamp study, still appeared active under the epithelium which covered it. The appearance suggested a deep corneal abscess which had healed on the surface. It was difficult to maintain good dilation of the pupil even with 2-percent atropine, 2 drops every 2 hours. A general survey of the patient had the following results:

Blood serologic findings and blood count normal; urinalysis normal; X-ray studies of the chest, sinuses, and teeth, negative. The tonsils were surgically absent. Prostatic examination revealed a chronic nonspecific prostatitis with 40 to 50 white blood corpuscles present in each high-power field. The prostatitis was treated by gentle massage at weekly intervals.

Fever therapy was advised and instituted on July 26th. Therapeutic time, 2 hours at $104.5^\circ F.$; elevation time 3 hours, 10 minutes. *July 28th.* Therapeutic time 2 hours, at $104.4^\circ F.$; elevation time 3 hours. *August 3d.* Therapeutic time 2 hours, at $105.4^\circ F.$; elevation time 3 hours, 30 minutes. *August 8th.* Thera-

peutic time 2 hours, 5 minutes, at 104.4°F.; elevation time 3 hours, 10 minutes. *August 11.* Therapeutic time, 2 hours, at 105.4°F.; elevation time 3 hours, 15 minutes.

During this period of therapy atropine and hot compresses were continued. Response to fever therapy in this case was most gratifying. The eye became white and quiet at once. The deep corneal infiltrate was rapidly absorbed. The lid edema subsided, and the secondary iritis and photophobia disappeared. The ulcer remained solidly healed. Atropine was discontinued on August 17th, following which the eye remained quiet. Vision with correction on August 30th was: O.D. 20/20-3, J1, with -2.25D. sph. \ominus +.75D. cyl. ax. 128°.

Impression. The corneal ulcer was controlled and superficial healing attained with penicillin therapy, atropine, and hot compresses. The deep corneal infiltration, secondary iritis, and congestion of the globe, did not subside until fever therapy was given.

CASE 6. IRIDOCYCLITIS. E. B. J., aged 23 years was admitted to the Eye Service, Billings General Hospital, on April 27, 1944, because of severe pain, photophobia, and some blurring of vision of the right eye of one week's duration. Vision on admission was: O.D. 20/20-3, blurred, O.S. 20/20.

Examination showed an acute iridocyclitis of the right eye, with marked edema of the lids. The iris was two-thirds dilated and irregular because of posterior synechiae (atropine had been instilled prior to the patient's admission here). Slitlamp study showed numerous K.P. The aqueous was filled with non-moving cells suspended in a gelatinous exudate. The iris was muddy and engorged. The lens was clear and the fundus normal. The ocular tension was 15 mm.

Hg (Schiøtz). Local treatment instituted consisted of 10-percent neosynephrin drops, one in the eye three times daily, together with atropine 2-percent drops, two every three hours and hot wet compresses for 20 minutes, every two hours.

Fever therapy was given as an emergency, for it was feared this patient might develop a secondary glaucoma from obstruction of the iris angle with exudate and cells from the anterior chamber. This therapy was administered as follows:

April 27th. Therapeutic time 1 hour, 40 minutes, at 105.6°F.; elevation time 2 hours, 45 minutes. *April 28th.* Therapeutic time 2 hours, 5 minutes, at 105.4°F.; elevation time 3 hours. *May 1st.* Therapeutic time 2 hours, at 105.8°F.; elevation time 3 hours. *May 5th.* Therapeutic time 2 hours, 5 minutes, at 105°F.; elevation time 3 hours, 30 minutes.

Sulfadiazine and sodium bicarbonate, of each 1 gram, were administered every 3 hours for 4 doses preceding the first two fever treatments. Because of the development of a mild sulfadiazine urticaria, the chemotherapy was omitted in the other two treatments. Response to fever therapy in this case was spectacular, all lid edema had disappeared on the day following the first fever elevation. In addition, the eye had become free of pain and full pupillary dilation had been secured. Slitlamp study on that day showed a marked clearing of the aqueous with cells much fewer in number and actively moving in the convection currents.

Following the completion of fever therapy, the general survey for foci of infection was carried out. Some chronically diseased tonsils were removed and a mild nonspecific prostatitis was cured by periodic massage. Convalescence was uneventful with no evidence of recurrence of the iridocyclitis.

CASE 7. PENETRATING FOREIGN BODIES INTO THE VITREOUS CHAMBER. G. W. J., aged 23 years, was admitted to the Eye Service, Billings General Hospital, on April 27, 1944, for treatment of a retained metallic foreign body in the left eye, accidentally incurred three days previously. Vision was: O.D. -20/20, J1; O.S. light perception with faulty light projection. X-ray studies and localization showed the foreign body to be $4\frac{1}{2}$ by 2 by 2 mm. in size, lying behind the lens in the inferior nasal quadrant of the globe. The wound of entry through the ciliary body in the temporal quadrant at the 3-o'clock position, had been closed at another hospital. The lens was clear. The vitreous was filled with blood, and no red fundus reflex could be made out. The foreign body was removed with the hand magnet on April 28th, through a peripheral iridectomy at the 9-o'clock position. Fever therapy was begun on the day of operation and continued as follows:

April 27th. Therapeutic time 1 hour, 30 minutes, at 103°F.; elevation time 2 hours, 35 minutes. *April 28th.* Therapeutic time 1 hour, 30 minutes, at 104.3°F.; elevation time 3 hours, 15 minutes. *May 1st.* Therapeutic time 2 hours, at 104.4°F.; elevation time 3 hours, 15 minutes. *May 4th.* Therapeutic time 2 hours, at 104.4°F.; elevation time 3 hours, 10 minutes. *May 6th.* Therapeutic time 2 hours, at 104.2°F.; elevation time 3 hours, 15 minutes. *May 12th.* Therapeutic time 2 hours, at 105°F.; elevation time 3 hours, 30 minutes.

Fever therapy was instituted as an emergency in this case because of the fear of intraocular infection. Two cilia carried into the vitreous chamber were extruded through the wound of entry and removed on May 10th and 17th, respectively. In spite of the fact that these cilia had been carried into the interior of the globe by the foreign body, this eye remained en-

tirely quiet, white, and free of pain.

On May 19th a mild, quiet iridocyclitis was noted on slitlamp examination. Vision in the eye had been lost because of the massive vitreous hemorrhage first noted on the day of admission. The eye was enucleated on May 20, 1944, because of the fear of sympathetic ophthalmia and because the vision of the eye was obviously hopelessly lost because of vitreous hemorrhage and retinal detachment. The pathologic report on this eye showed massive vitreous hemorrhage with retinal detachment and a chip of paint (chrome green) imbedded in the retina near the optic disc. Loss of the eye obviously cannot be charged to the failure of fever therapy. This case is presented for two reasons:

(1) To show that fever therapy in the fever cabinet can be safely given on two successive days. (2) This eyeball remained white and quiet and free of pain following the injury and subsequent surgical removal of a metallic foreign body in spite of the presence of two cilia in the vitreous chamber for 16 and 23 days, respectively, and a particle of paint imbedded in the retina. We believe that the fever therapy played a role in keeping the eye comfortable, quiet, and free of supuration.

CASE 8. RETROBULBAR NEURITIS, ACUTE, RIGHT, CAUSE UNKNOWN. N. J. R., a white corporal, aged 26 years, was first seen in the Eye Out-Patient Department at Billings General Hospital on July 7th, because of a sudden onset of "blindness" in the right eye and pain behind the eye on ocular movement. He stated that this had occurred about five days previously. Vision was: O.D. 2/200 not correctable; O.S. 20/200 correctable to 20/50.

This patient had worn glasses since childhood for the correction of a high degree of compound hyperopic astigma-

tism and a moderate right convergent strabismus. The right eye had been "straight" for the past 10 years. He stated that the vision had never been corrected to better than 20/70 O.D. and 20/50 O.S. Refraction under homatropine on July 7th was:

O.D. +5.00D. sph. \approx +1.00D. cyl. ax. 75° = 2/200; O.S. +5.00D. sph. \approx +.75D. cyl. ax. 120° = 20/50.

Both eyes were externally and internally normal. Peripheral field studies were normal. Central field studies showed an 8-degree absolute central scotoma, O.D. A diagnosis of retrobulbar neuritis was made. A general survey revealed no evidence of foci of infection in the mouth, throat, nose and sinuses, or prostate. The blood-serology, blood-sugar, and sugar-tolerance tests were negative. A careful neurologic examination for evidence of multiple sclerosis was entirely negative on two occasions. The patient did not use alcohol or tobacco.

He was treated in the Out-Patient Department for one week. This treatment consisted of thiamin 250 mg. daily by intravenous injection, and 10 mg. three times daily by mouth, and nitranitol 0.25 grain by mouth morning and evening.

Because there was no improvement in visual acuity after six days, the patient was hospitalized, so that fever therapy

might be administered as follows:

July 15th. Therapeutic time 2 hours, 5 minutes, at 104.6°F. ; elevation time 3 hours, 10 minutes. *July 19th.* Therapeutic time 2 hours, at 104.2°F. ; elevation time 3 hours, 20 minutes.

The visual acuity with correction on the day following the first fever treatment had improved from 2/200 to 20/80. Following the second fever therapy, this had further improved to 20/70. No further improvement in acuity was noted and the patient stated the acuity was then as good as it had ever been. It was our opinion that the partial residual amblyopia was probably from disuse, an incident of his strabismus in childhood and high hyperopic refractive error.

CONCLUSION

Artificial-fever therapy is a safe and certain method of treatment by which therapeutic temperature elevations can be easily attained with a minimum of discomfort to the patient. It has many advantages over triple typhoid vaccine. In ophthalmology excellent results have been attained with short treatment periods of not over 105°F. for two hours. When available it should be considered the method of choice in those diseases of the eye in which adequate and repeated fever therapy may be a sight-saving measure.

SOME OBSERVATIONS ON DIVERGENT STRABISMUS WITH ANOMALOUS RETINAL CORRESPONDENCE*

HENDRIE W. GRANT, M.D.

Saint Paul, Minnesota

Strabismus incongruus was first described by Johannes Müller,¹ although exactly what he regarded as incongruous strabismus is a little difficult to understand. The type of strabismus to which he referred was apparently congenital and incurable, depending upon the difference in the position of the identical points of the retinas of both eyes from a subjective standpoint, the identity in the two eyes belonging to different meridians with the central point in one eye corresponding to an identical point in the other eye which is removed from the central point. At the same time, however, by the use of pressure phosphene he gave an accurate description of corresponding retinal points, which is apparently the first reference to such points. The use of local pressure on the eyeball to produce a luminous effect has been known since the time of Aristotle. Hering,² in 1863, by the use of afterimages found a similar localization of corresponding retinal points.

Donders³ was somewhat confused by Müller's statements and believed that he referred only to an apparent strabismus with either a positive or a negative angle. However, Alfred von Graefe⁴ described a very classical case of incongruence of the retina through displacement of the optic nerve. This he described as due to the macula, together with the optic nerve, being strongly displaced inward. He cited, likewise, another case⁵ of true incongruence of the retina in which the macula is said to have occurred at the nasal side of the optic nerve in one eye. Furthermore, von Graefe discussed the subject

somewhat in detail in a clear manner⁶ although Arlt⁷ was still somewhat confused by his description. He believed, however, that these were not true incongruities of the retina but asymmetrical development of the two halves of the eye. Both Donders⁸ and Von Jaeger⁹ believed these to be cases of apparent strabismus without actual deviation of the visual axes.

Duane,¹⁰ in discussing the subject of retinal incongruity in general, gives to von Graefe credit for the original discovery. In 1842, Pickford¹¹ had previously described the first instance of a true retinal incongruity, later to be followed by a large number of similar observations. Duane points out the fact that retinal incongruity is frequently associated with horror fusionis, which von Graefe called "Antipathy to single vision," and cites the close relationship between incongruity and horror fusionis. In a review of 42 cases of incongruity, he cited 9 which were exotropic and 5 others which were exotropic with vertical deviation. One case given in detail cites the case of a boy, aged 18 years, who had had a divergent strabismus since the age of two years. Operations had been performed upon one eye when he was 12 years old and upon both eyes when he was 16. There was a resulting diplopia and marked asthenopia and only 3 degrees of objective deviation. Images were fused with the amblyoscope, however, only when the tubes were converged 30 to 40 degrees. Correction of the refractive error caused disappearance of the diplopia and asthenopic symptoms.

Concerning divergent strabismus, Bierschowsky¹² pointed out that, while perfect binocular vision and depth perception

* Candidate's thesis accepted for membership in the American Ophthalmological Society, June, 1944.

might be present even with good fusional amplitude during latent periods of divergent strabismus, diplopia is absent during the manifest periods of squinting. Likewise, if diplopia images are produced by any one method, they will not be crossed but will show an anomalous retinal correspondence approximately equal to the divergent position of the eyes. Prisms, base in, produce diplopia. With vertical prisms the objects are seen one directly above the other or with only a very slight lateral displacement. In the afterimage test of Hering, the vertical image belonging to the right eye is displaced more or less to the right of the center of the left afterimage. One gains the impression from his description that the correspondence in such instances is normal during the latent period and anomalous if the squinting is manifest. He feels that in every case of constant divergent strabismus an anomalous correspondence will be found, with alternate suppression of the squinting eye. Likewise, he warns, horror fusionis frequently occurs and should be looked for in every case of alternating divergent strabismus. Following surgical correction of the strabismus, homonymous diplopia is likely to be present and to persist for a longer or shorter period of time until there is orthophoric suppression or binocular vision is reestablished.

Concerning the operative correction of such cases, he described in detail one case. He states: "There are cases of divergent strabismus, fortunately rare, which baffle the doctor in spite of the greatest care and experience and the greatest skill as to operative technique." A boy, aged 5 years, with 30-degree divergent strabismus and poor convergence underwent an operation in which advancement of both internal recti combined with recession of both external recti was performed. A 20-degree divergence remained. Three years

later advancement of both internal recti was repeated and the divergence reduced to 12 degrees, which increased to 26 degrees within the next month. "In addition to the ordinary sutures, auxiliary double-armed needles were passed through the body of the muscles and fastened beyond the vertical meridian both above and below." The immediate effect was excellent, but divergence developed again and increased to 30 degrees within three months. Adduction was poor, both before any surgical attempt was made and before the third operation was attempted. Bielschowsky believed that the defect might have been due to some congenital anomaly, which defect he was never able to discover, even after the most careful search, and he was unable to account for the very unsuccessful result. He does not state, however, whether or not anomalous retinal correspondence was present.

Concerning development of anomalous correspondence Bielschowsky¹³ states that little is known except that investigators agree that it seldom occurs in squint arising after the sixth year. Exceptions occur, however, in some individuals with high exophoria in whom a latent squint becomes a manifest divergent strabismus but reveals no evidence of diplopia. When double images are produced by the red glass and prisms, there is an homonymous diplopia showing the characteristics of anomalous retinal correspondence adapted to the angle of the strabismus. He feels, likewise, that, because of the unstable nature of the anomalous correspondence, the time-consuming effort to determine its presence or absence is a matter of questionable value. It is entirely within the realm of possibility that the correspondence in the aforescribed, very unsuccessful case of divergent strabismus was never determined.

The question of anomalous retinal correspondence in divergent strabismus has

received little or no attention except by Duane and Bielschowsky. Howe,¹⁴ Savage,¹⁵ and Worth¹⁶ do not mention the subject. On the other hand, Chavasse¹⁷ states that normal sensory correspondence is particularly common in divergent strabismus, especially if intermittent. This is also true even if there is an insufficiency of convergence at an early date. He does subscribe, however, to the remark of Bielschowsky that anomalous retinal correspondence may occur in older individuals in whom a latent exotropia may become a manifest divergent strabismus. He cites also one case¹⁸ of a girl, aged 12 years, who had alternating divergent strabismus with good convergence, who had at times a normal and at other times an anomalous retinal correspondence. Duane¹⁹ found and admitted cases of divergence excess, in whom the convergence is normal in spite of the high exophoria.

The subject of divergent strabismus apparently involves two definite classes of cases. The first comprises those individuals who at an early age have a spasm of one external rectus when the eyes are focused upon a distant object. This type of strabismus is definitely intermittent in character and remains latent most of the time. Strabismus is no more pronounced nor frequent when the child is fatigued. Spasms of one or the other eye outward may occur at any time of the day, the strabismus disappearing and binocular fixation assumed if the child's attention is focused upon the defect. The movement of recovery in producing binocular fixation is brought about either by a blinking of the eyes or a voluntary fusional effort. The strabismus remains intermittent and becomes manifest only when the individual is relaxed. Diplopia is generally absent. Should the deviation reach the degree at which voluntary fusional efforts are insufficient to produce binocular fixation for distant objects, it may still be

produced for near objects. In many instances an individual may have an intermittent or even a constant divergent strabismus for distance and binocular fixation at one-third meter. Asthenopic symptoms occur when the eyes are used for reading or other close work, are apparently due to the extremely high exophoria, and may be present in spite of a normal convergent near point.

Convergence usually remains intact and oftentimes normal in spite of high degrees of deviation for both distant and near objects. One individual, who had a constant divergent strabismus of approximately 70 arc degrees alternating in character, was able to produce binocular fixation for near by the aid of a looking-glass. I believe that the ability to produce binocular fixation for near, in spite of a high degree of deviation for distance, is the most important single test for the successful outcome following surgical intervention. Thus, an individual may at times have an anomalous correspondence adapted to the angle of the deviation, but the anomalous correspondence is not constant and may be varied according to the state of the muscle balance itself. Should diplopia occur in such cases following surgical intervention, it is due to a temporary overcorrection or lack of external rotation and is definitely homonymous in character. I have never seen it persist except for a short period of time.

I have not failed to find a successful surgical result in any individual who is able to produce binocular fixation, spontaneously or with voluntary fusional effort, in any case of divergent strabismus. It would appear that this strabismus arises as a pure divergence-excess anomaly, and, although the exophoria for the near point is increased as a result of anatomic changes in the muscles, produced by the spasms and relaxations of the external rectus, the convergence func-

tion itself remains intact and is not ultimately broken down by the divergence excess. Davis²⁰ has reported an excellent example of this type of anomaly. It would appear that a purely divergent type of anomaly does not have the deleterious effect upon the fusion center that is true in the case of the convergent anomalies.

The second class comprises a much more infrequent type, in which the strabismus is constant in character in the absence of voluntary fusional efforts to produce binocular fixation. Amblyopia may be and more frequently is present than in the first type described. Some degree of hypertropia is generally present, but no true cases of double hyperphoria were found in this type of anomaly. The deviation usually begins shortly after birth or even as late as the age of adolescence. The amount of deviation is fairly constant, both for distance and near, and is, in the vast majority of cases, greater than or equal to the amount of deviation for distance. Convergence in four cases out of five is faulty. I do not believe that the convergence function is paralyzed, for it can be greatly improved by exercise, but it does not approach the normal convergent power. The anomalous correspondence is constant in that it is never normal and then anomalous. The fusion is extremely poor; sometimes first-degree fusion may be present but oftentimes even this is lacking, which in all probability accounts for the discrepancy between the findings of the correspondence on the synoptophore, the red glass, and the afterimage test. I believe that the former are more conclusive than the latter as an indication for surgical correction. It is in this group of cases that surgical intervention results either in a gradual increase in the amount of deviation, until the original amount is assumed, or in a constant asthenopia which is extremely difficult to relieve.

I have attempted in every case to elimi-

nate all possibilities of either traumatic or infectious involvement of the convergent center and was surprised to find that even small children, who had definite evidence of injury to the convergent center, either as a result of trauma or encephalitis, did not show the usual characteristics of anomalous retinal correspondence. The visual factor in all probability plays an important part.

In 4 cases out of 15 there was definite amblyopia, which is a high percentage as far as divergent strabismus itself is concerned. Likewise, in the only case observed, in which the anomalous correspondence disappeared spontaneously, it was apparently dependent upon an increase in the visual acuity rather than upon any change in the muscle balance. In those cases in which the patient was submitted to surgical treatment the immediate outcome of the surgical intervention was entirely satisfactory, but the deviation increased within a short period of time. The anomalous correspondence was always adapted to the angle of deviation; it decreased with surgical intervention, and increased simultaneously with the deviation itself. In the course of a month or two it usually assumed its original characteristics and amount.

It is interesting to note that in those cases in which there was a combined vertical deviation the incongruity of the images was present sometimes for the lateral and sometimes for both deviations. Fusion, however, was so poor in every instance that diplopia did not occur as a result of the surgical treatment.

In some instances, in which divergent strabismus has resulted from a previous convergent strabismus at some time after the age of puberty, an anomalous correspondence adapted to the angle of the deviation is sometimes found. In others, the correspondence is normal, and diplopia occurs as soon as one eye diverges. The same is likewise true in those cases

in which a divergence has resulted from the surgical overcorrection of a convergent strabismus. In these instances, however, the anomalous correspondence rapidly disappears following the surgical correction of the divergent strabismus. Convergence exercises would seem to produce more beneficial effects than any other type of therapy, but it is not believed that the improvement is maintained, even though the correspondence is adapted to the angle of the strabismus as the improvement results. It is not felt that convergence exercises, unless maintained constantly, would prevent the strabismus from assuming its original angle of deviation.

In a small group of cases there is apparently a type of divergent strabismus that arises as a result of divergence excess with an apparently constant and unvariable anomalous retinal correspondence, yet which has good convergence and sometimes binocular fixation for the near point of one-third meter. When, however, any attempt is made to correct the strabismus, either by the use of prisms or by surgical intervention, an immediate diplopia or constant asthenopia results. This is well illustrated by case 3 in group 2 of this report, and also by the similar case reported by Duane.²¹ The nonsurgical treatment would seem to be quite as unsatisfactory as surgery itself. Subjective symptoms are generally lacking. A decrease in the amount of deviation or a change in the type of the correspondence does not result from the use of orthoptic exercises.

The four surgical cases here reported in group 1, in which the strabismus had a tendency to resume the original angle of deviation following surgical correction, would seem to correspond in almost every detail to the case reported by Bielschowsky. It is my belief that in these cases the faulty functioning of the convergence center is the primary cause of

the poor surgical result. These must be contrasted with case 3, group 2, and the similar case reported by Duane, in which there was a successful correction of the deviation itself but an anomalous correspondence adapted to the previous angle of deviation. It is possible that over a period of years correspondence might return to normal, as there was every evidence in case 3, group 2, that the anomalous correspondence was gradually becoming more normal as evidenced by the fusion of images when the tubes were converged from 15° to 40°, six years after the last operative procedure was performed.

Group 3 represents definite instances of horror fusionis. The individual in whom horror fusionis might possibly be present has a condition for which every ophthalmic surgeon should be constantly on the alert. The classical method of diagnosis, as described by von Graefe, in which it is impossible to produce fusion of the images with any correction of the deviation and a marked increase in the deviation itself with slight overcorrection, needs no further emphasis. Both the correction of the deviation itself with prisms and by surgical correction results in a most distressing type of asthenopia or diplopia. As stated previously, the deviation itself generally produces no cosmetic defect. Binocular fixation and binocular vision are likely to be present at one-third meter, while constant deviation of the visual axes from six meters to infinity is often present. Very great care in the correction of the refractive error usually results in the complete and total cessation of all the subjective symptoms, and the condition itself would seem to be dependent upon a defect in the sensorial as much as upon a defect in the motor apparatus and the various pathways.

It might be argued that the three cases represented in group 2 belong in the definite category of horror fusionis with

a high degree of deviation. I do not believe, however, that they can be placed in this group, for there was not the least attempt on the part of any one of these individuals to fuse images with a partial or total correction of the deviation present. Even the slightest correction of the deviation produced a constant and insurmountable diplopia. In the first two cases of this group the convergence function was carefully studied and found to be normal. In the other instance the convergence function was found to be satisfactory following surgical treatment elsewhere, and it is assumed that it was good or normal before surgical intervention. Although the convergence function may be fairly good in *homo fusoris*, it does not seem possible to classify these cases in that group.

The following record is the report of 22 cases of divergent strabismus which have been followed over a period of months or years, and from which certain deductions are drawn. The cases fall roughly into the three main groups previously described.

The first group of 15 cases comprises those with constant divergent strabismus of small or high degree with total anomalous correspondence, poor convergence, and poor fusion, in which it seems impossible to correct the divergence medically or surgically. The age of onset in each instance was early in life, at or shortly after the age of puberty. In one case the onset was at 22 years of age, while in another it was thought to be present from birth. Heredity apparently played no prominent part except in three patients, who were said to have had relatives with a similar condition. Amblyopia was present in four cases, with vision of 20/60, 20/70, 20/30, and 20/200 in the amblyopic eye with correction of the refractive error. The amount of deviation was approximately equal for distance and

near, or slightly greater for near in every instance. In 4 of the 15 cases there was an associated hyperphoria that ranged from 2^{Δ} to 18^{Δ} . The hyperphoria was always concomitant. In some of the other cases the presence or absence of hyperphoria was impossible to determine subjectively. The amount of deviation varied from 18^{Δ} to 90^{Δ} , deviation of 40^{Δ} to 50^{Δ} being the usual amount.

The correspondence was checked in each instance by the use of the red glass, the synoptophore, vertical prisms, and the afterimage test. The anomalous correspondence was total in 12 cases and partially total in three. In one instance there were 90^{Δ} objectively and 12^{Δ} subjectively; in another 20^{Δ} objectively, 4^{Δ} subjectively; and in another 18^{Δ} objectively and 10^{Δ} subjectively. The convergence function was poor or nil in every instance. There were no instances in which a definite paralysis either of the lateral or vertical recti could be demonstrated, and there was no history of a previous traumatic or infectious paralysis of convergence function. None of the cases gave previous history of original convergent strabismus. The fusion was poor in all cases, although sufficiently good in one instance to measure the subjective deviation by the use of the phorometer. In some instances the fusion was so poor that the afterimage test was not reliable. In these instances the individual had a tendency to form a more or less perfect cross with the afterimage test, whereas with the synoptophore or red glass there was total anomalous correspondence. In one instance the vertical portion of the cross was definitely oblique, indicating oblique involvement, although the fusion was so poor as to make a subjective measurement of the vertical deviation impossible. The afterimage test would, however, seem to be a very valuable adjunct in testing the nature of the correspondence. Diplopia was not

present in any instance, although at times it might be induced by the use of the red glass and prisms, base in, to correct the deviation. In such cases the diplopia was always incongruous in nature. None of these individuals was able to produce binocular fixation for distance or near vision, either with spontaneous or voluntary fusional effort.

Three methods of treatment were instituted in these cases for the relief of the deviation and improvement of the cosmetic defects: (1) Orthoptic training; (2) convergence exercises; (3) surgery. In each instance the fusion was so poor that the orthoptic training proved to be of little or no value. Convergence exercises, when it was possible to use them, temporarily reduced the amount of deviation present, but the deviation increased as soon as the exercises were discontinued. In one instance the exercises were continued because of the presence of asthenopia and an increase in the deviation as soon as the exercises were discontinued. Four cases of this group were treated surgically, all of which were unsuccessful in the outcome.

CASE REPORTS

Case 1. E. M., a girl, aged 16 years, developed a divergent strabismus early in childhood. She was a ward of the state, and no information could be obtained about her heredity or early childhood. She had worn glasses since 1936, although the refractive error was practically nil. There was a deviation of 55^Δ for six meters and 57^Δ at one-third meter, combined with 8^Δ of left hypertropia. With the synoptophore the soldier was put in the house at zero degrees, making total anomalous correspondence. The after-image test also showed total anomalous correspondence.

On September 18, 1940, the right external rectus was recessed 2 mm.; the right internal rectus resected 4 mm. On

October 30, 1940, the deviation was 58^Δ for distance and at one-third meter. January 1, 1941, the deviation was 44^Δ of exotropia for distance and 44^Δ of left hypertropia at one-third meter; January 4, 1941, 50^Δ of exotropia, 3^Δ of left hypertropia for distance and near. December 16, 1941, at 2½-mm. recession of the left external rectus and a 5-mm. resection of the left internal rectus were performed. The immediate effect on January 7, 1942, was 18^Δ of exotropia for distance and 23^Δ of exotropia for near, which increased by February 25th to 26^Δ for distance and 43^Δ at one-third meter. At this time convergence exercises were instituted which achieved an immediate improvement to 15^Δ of exotropia for distance and 26^Δ diopters for near. These values remained the same for several months under exercise, but gradually increased as soon as the exercises were discontinued. Binocular fixation could not be induced for either distance or near vision.

Case 2. R. B., a boy, aged 13 years, had had a periodic divergent strabismus, limited to the right eye; since the age of two years. The right eye was also amblyopic, having a vision of 20/60 both corrected and uncorrected. There was a deviation of 34^Δ for distance and 48^Δ for near, with approximately 2^Δ of right hyperphoria with the red glass. There was total anomalous correspondence with the red glass and also with the afterimage test. Convergence was nil. The fusion was so poor as to make the use of the synoptophore unreliable. There was partial suppression with the red glass and occasional diplopia with correcting prisms.

On April 8, 1942, the right external rectus was recessed 3½ mm., and the right internal rectus resected 4 mm., with resulting correction of 14^Δ for six meters and 18^Δ at one-third meter. The convergence function was not improved and images were still superimposed at zero

degrees. Diplopia was not present. In February, 1943, the deviation had increased to 22° at six meters and 33° at one-third meter. Some slight degree of right hyperphoria or a very slight double hyperphoria was still present. The anomalous correspondence was not changed by the surgical procedure, and the deviation was gradually increasing.

Case 3. C. E., a woman, aged 45 years, had a divergent strabismus of the left eye which had been present from birth. The vision of the right eye was 20/20, left eye 20/25, with the right eye fixating more or less constantly. The deviation measured 70° for six meters and 78° for one-third meter. Convergence was nil. In the afterimage test there was normal correspondence with a more or less perfectly formed cross. Fusion was very poor and diplopia was induced with difficulty.

On January 29, 1942, a complete tenotomy of the left external rectus and a 6-mm. resection of the left internal rectus muscle were performed. The immediate effect of this operation was to reduce the deviation to 50° , a 20° improvement as a result of the surgical procedure. The condition remained practically unchanged during the next week, or perhaps with a slight increase in the amount of deviation. The correspondence was again checked and found to be what was considered a perfect cross on the afterimage test. With the red glass and prisms, however, there was total anomalous correspondence. Fusion was so poor that simultaneous macula perception could not be demonstrated on the synoptophore.

On December 22, 1942, the following surgical procedure was carried out: The left internal rectus was resected 3 mm. and advanced $1\frac{1}{2}$ mm. The right medial rectus was resected 5 mm. and advanced $1\frac{1}{2}$ mm. The left external rectus was again freed and recessed fully to the equator of the eyeball. The immediate effect of the surgical procedure was very

satisfactory in that the deviation was reduced to 10 degrees when the patient was discharged from the hospital. In January, 1943, the deviation had increased slightly to 30° for distant and near vision, and in May, 1943, the deviation measured 45° for both distant and near vision. The total net result of all the operative procedures had been a decrease of 20° to 25° in the total amount of deviation.

Case 4. E. F., a girl, aged 10 years, had had a divergent strabismus of the right eye since the age of four years. She had worn glasses which had not improved the deviation; there was no evidence of any hereditary influence as a causative factor in her condition. The vision of the right eye was 20/40, of the left eye 20/20. The deviation measured 50° of exotropia and 16° of left hypertropia for six meters and one-third meter. Convergence was practically nil. Both the afterimage and the red-glass tests showed total anomalous correspondence. The right vertical afterimage was 39 cm. to the left and 11 cm. above the central point. There was 16 diopters of hyperphoria in the six cardinal directions of the gaze.

In October, 1940, the right external rectus was recessed $2\frac{1}{2}$ mm. and the right internal rectus resected 5 mm. The immediate effect of the operation was satisfactory, with no untoward reaction. The patient was reexamined in February, 1941, at which time the deviation was 50° of exotropia and 16° of left hypertropia for six meters and one-third meter. This deviation gradually became stationary in the next few months, showing a final measurement of 40° of exotropia and 16° of left hypertropia at six meters and 42° of exotropia and 16° of left hypertropia at one-third meter—a very slight improvement from the operative procedure. No further surgery was contemplated because of the unsatisfactory result obtained.

Group 2 represents apparently a much more uncommon divergent anomaly than the first, the chief difference between the two being the state of the convergence function. In this group, which comprises only three cases, there is poor fusion, total anomalous correspondence, good convergence function, and likewise the absence of any subjective symptoms except asthenopia. Two of the cases occurred in identical twins and might be reported as a single case, as they are almost identical. As stated previously, it might be argued that these three cases are instances of horror fusionis with a higher-than-usual degree of deviation, as the convergence function was good in each instance. I do not believe, however, that they can possibly be classified as true cases of horror fusionis.

Cases 1 and 2 are those of identical twins, aged 14 years, who had had divergent strabisms since the age of two years. They had been treated since that time by glasses and orthoptic exercises. There was a gradually increasing divergent strabismus in both cases, but no subjective symptoms except asthenopia. In one—T S—the refractive error was: R.E. $-1.50D.$ sph. $\approx -0.25D.$ cyl. ax. 45° ; L. E. $-0.25D.$ cyl. ax. 90° . The vision was equal with the left eye dominant. The deviation measured 24^Δ exotropia for distance and 12^Δ for near, with square prisms. There were two diopters of esophoria on the phorometer. Convergence was excellent. There was first-degree fusion on the synoptophore, suppression with the red glass, and total false correspondence. Diplopia was present as soon as any attempt was made to correct the divergence, which was constant for distance. At one-third meter there was binocular fixation, with a movement of recovery of either eye and normal convergence. There was normal correspondence on the afterimage test,

although a slight tendency of the horizontal meridian to be tilted. No treatment was instituted, except correction of the refractive error.

In the other twin—R S—the refractive error was R.E. $-25D.$ cyl. ax. 90° ; L. E. $-1.25D.$ sph. $\approx -25D.$ cyl. ax. 45° . With the square prisms there was deviation of 26^Δ for distance, 12^Δ for near, and 2^Δ of esophoria on the phorometer. Convergence was good. Prisms, base in, produced diplopia and, base out, produced suppression. There was total anomalous correspondence with the red glass and practically normal correspondence with the afterimage test. First-degree fusion only was present. No subjective symptoms were present when the glasses were worn constantly.

Case 3. E. B., a man, aged 34 years, had had a divergent strabismus that restricted him to the use of only one eye at a time, for at least the past 16 years. In 1935, he had had some orthoptic training from an optometrist. Later in the same year a recession of the left external rectus had been performed by one physician, and in 1936 a resection of the left internal rectus by another.

When first seen, in April, 1941, he complained of having had severe asthenopia and headache since the surgery, but he was quite free after a night of rest. As a bookkeeper he had considerable difficulty in performing his usual duties. Visual acuity was 20/20 in each eye, and there was practically no refractive error. No cosmetic defect was present, and there was no evident deviation of the visual axes. With square prisms and the screen test there were approximately 5^Δ of exophoria and an incongruous diplopia of approximately 40^Δ on the phorometer. With the synoptophore he was able to fuse when the tubes were converged from 20^Δ to 40^Δ , and had no more than first-degree fusion. Diplopia was absent at all

times and suppression was present with the red glass. The convergence function was excellent but tended to be excessive rather than weak. It is possible that a definite convergent spasm was present. No treatment was instituted except the correction of a small amount of astigmatic error, although the symptoms gradually became less pronounced, and in the course of two years he was able to carry on his usual duties with much less discomfort. The incongruous diplopia seemed to be gradually decreasing, as he was able to fuse on the synoptophore at approximately 15^{Δ} whereas previously 20^{Δ} was the best that he could accomplish.

Case 3 is placed in this group because of the presence of good convergence function, as it is believed that, if the identical twins had been subjected to surgery, they would show the same characteristics as in case 3; namely asthenopia, correction of the divergent deviation, and incongruous diplopia. There is nothing of importance in the heredity of these twins, except that the mother has a convergence excess and shows approximately 2^{Δ} of esophoria for distance, 22^{Δ} of esophoria for near, but with binocular fixation at all times. There was a history at one time in the boys' mother of a severe asthenopia while going to college, occasioned by an emotional upset. These three instances seem to indicate anomalous correspondence arising in an individual, with divergent strabismus due to divergence excess. Although the condition is correctable surgically, the aftersymptoms of asthenopia and headache might not warrant the correction of the cosmetic defect in the absence of severe subjective symptoms.

Group 3 represents a series of four cases in individuals in whom there is a more or less constant deviation for distance, binocular fixation for near, with

subtotal or total anomalous correspondence, and with classical findings of horror fusionis. The deviation in these cases never exceeded 28^{Δ} , was greater for distance than for near vision, with good fusion and with good convergence in one instance. There was, however, an entire absence of the amplitude of fusion. Fusion was poor except in the one instance, mentioned, and in this individual there was a tendency toward diplopia when fatigued. The anomalous correspondence was either totally or partially anomalous. Binocular fixation was apparently present in each instance at one-third meter and only once at six meters. Amblyopia was not present in any instance. Any attempt to correct the total deviation was occasioned by a spontaneous diplopia, incongruous in nature, with inability to overcome the diplopia present. Symptoms of asthenopia were generally marked and greatly increased by the use of prisms, base in, for the correction of the deviation present. Meticulous care in the correction of the refractive error resulted in every instance in a complete relief of the symptoms present. In no instance was there a definite noticeable cosmetic defect. Symptoms were definitely increased with fatigue and emotional stress.

In addition to the aforementioned three groups, one case (No. 12, group 1) is reported in detail because of a spontaneous disappearance of the abnormal retinal correspondence occasioned by an improvement in the visual acuity.

B. B., a woman, aged 22 years, had been under observation since the summer of 1938, when she suffered an injury to the left eye. At this time a small pin dart pierced the cornea of the left eye near the limbus, passing through the iris and entering the lens posterior to the equator. This produced an opacity on the posterior

lens capsule and cortex, similar to that seen in cataracta complicata, with a consequent reduction in vision to approximately 20/200. This opacity on the posterior cortex gradually became stationary, and the vision improved with a $-1.50D.$ sph. to 20/65. The refractive error of the right eye was low hyperopic astigmatism. As vision gradually improved, severe asthenopia developed. Binocular fixation for distance and a constant divergent strabismus for near were present. At this time there were 15^Δ of exophoria at one-third meter with square prisms, no fusion, no subjective deviation on the phorometer, total anomalous correspondence on the synoptophore, and suppression with the red glass. Images were always fused at zero degrees on the synoptophore. There was a slow but gradual change in the refractive error, which changed from $-1.50D.$ sph. to $+1.00D.$ sph. $\approx +1.50D.$ cyl. ax. 120° . With this lens there was 20/50-2 vision and a marked improvement in the asthenopic symptoms. In November, 1942, a little more than two years after the original injury, there were binocular fixation for distant and near vision, normal correspondence, and 12^Δ of exophoria, both on the phorometer and the synoptophore. As soon as the correspondence returned to normal, there was a marked cessation of all of the asthenopic and subjective symptoms in spite of the marked difference in visual acuity in the two eyes. It would seem in this instance that the visual loss was responsible entirely for the production and maintenance of the abnormal retinal correspondence, and that correction of the refractive error was the most important single factor in the reduction of the symptoms and the return to normal of the retinal correspondence.

COMMENTS

As a result of this study of 22 cases of

divergent strabismus with anomalous retinal correspondence, a division into three primary groups has been made. The first group, with constant strabismus, poor fusion, and poor convergence, is the most difficult in which to secure satisfactory results. Neither the anomalous correspondence nor the poor fusion can be regarded as more than secondary factors in the tendency of the deviation to return to its original value. Consequently, the poor converging power must be the primary factor, as both poor fusion and anomalous correspondence are found in divergent strabismus in which the deviation can be reduced to a satisfactory cosmetic result. On the other hand, I do not consider the poor convergence a paralysis, as marked improvement resulted from exercise, even though maximum improvement was not maintained. In a small series of cases, with paralysis of convergence due to either trauma or encephalitis, I was able to produce little or no improvement following convergence exercises, even though these were conscientiously continued for some months. This group also had normal retinal correspondence. One should, therefore, carefully weigh all the factors before attempting surgical correction.

In the second group, with good converging power but a constant anomalous correspondence adapted to the angle of the deviation, a satisfactory cosmetic result may be secured. On the other hand, severe asthenopia and occasional incongruous diplopia are unpleasant consequences of surgical correction. Diplopia itself is not a distressing symptom after surgery, for, in every instance encountered both personally and in the literature examined, fusion was too poor to give rise to constant diplopia. Spontaneous disappearance of the anomalous correspondence does not apparently follow surgical correction, as is usual with the

convergent type. Whether the long period of discomfort and rehabilitation which follows the surgical correction in this group is justifiable for removal of the cosmetic defect, is one question which should be decided by the individual himself.

The third group comprises the not infrequent cases of horror fusionis. These are individuals with better fusion, a moderate divergent strabismus for distant or near vision, with marked asthenopic symptoms. Diplopia may frequently be present but not annoying, even though the cosmetic defect is small or absent. Although fusion may be fairly good, the amplitude of fusion is nil, and binocular vision is not possible with any correction of the deviation. The anomalous correspondence is partial or total, and constant in amount. Correction of the deviation, either by the use of prisms or surgery, results in a marked increase in asthenopic symptoms. Meticulous care in the correction of the refractive errors should produce complete relief.

SUMMARY

Twenty-two cases of divergent strabismus with constant anomalous correspondence have been studied from the standpoint of diagnosis and treatment. The fusion was so poor in some instances as to make the afterimage test unreliable.

From therapeutic results the cases are divided into three main groups:

1. Cases with poor convergence which were incurable, the deviation tending to assume its original amount and characteristics after surgical correction. Convergence exercises help to reduce the cosmetic defect but the improvement is not maintained.

2. Cases with good convergence in which the deviation can be corrected surgically. Severe asthenopic symptoms and incongruous diplopia are present for years after surgical correction.

3. Cases of horror fusionis with total or partial anomalous correspondence which are completely relieved by meticulous care in correcting the refractive error.

AMYLOID DISEASE OF THE CONJUNCTIVA*

NORMA B. ELLES, M.D.

Houston, Texas

Amyloid is a term used to designate a product that appears as a formed element in certain intercellular regions during the course of seemingly diverse pathologic states. It is characterized morphologically by its deposition in elective sites, its more or less dependable affinities for several unrelated stains, and its homogeneity. Recent work indicates that amyloidosis is not a degenerative disease, but the result of a long-continued metabolic disorder, probably protein in nature.

The disease is referred to briefly by Fuchs,¹ Collins and Mayou,² de Schweinitz,³ Berens,⁴ Wolff,⁵ and more in detail by Duke-Elder,⁶ who states that:

The disease attacks as a general rule young adults, especially between 25 and 30 years of age, affecting either one or both eyes; about two-thirds of the cases are bilateral. The degeneration is local and its cause is quite unknown, for the sufferers are almost invariably healthy and are not subjects of general amyloid disease; but it has a parallel in localized degenerations elsewhere—in the larynx (Courvoisier, 1902), the lung (Hersheimer, 1903), and the heart (Steinhaus, 1902). In the conjunctiva it usually begins in the transition fold, extending therefrom to the conjunctiva of the lid and the bulb. The mucous membrane appears yellow, transparent, waxy, and avascular, and in places may show swellings of considerable size. As the tarsus becomes involved the upper lids form two huge tumors of such size that the patient can hardly open his eyes; the entire conjunctiva and semilunar fold form irregular masses so brittle that they are readily torn (with, however, very little bleeding) when the lids are forcibly opened; and the cornea may be involved in the degenerative process, either the whole of it (Schreiber, 1913) or in a band-shaped area (Watanabe, 1922); alternatively, and more usually, it is disorganized by pannus.

The disease goes on slowly and inexorably and medical treatment is peculiarly ineffective. The only method of alleviation is surgical removal of the larger masses when their size and weight prevent the patient from lifting the lid sufficiently. If extensive removals are re-

quired the friable conjunctiva cannot make good the defect, and it is well to use a graft of mucous membrane of the lip. Complete removal of the mass is usually impossible and inadvisable; fortunately the remainder left behind has a habit of shrinking spontaneously, although gross recurrences have been recorded (Kubik, 1924).

An early case of amyloid disease of the conjunctiva came under my observation about three years ago, and I have had the opportunity to watch the condition periodically since then.

CASE REPORT

Mrs. H. A., aged 38 years, a beauty-parlor operator for the past 15 years, came for examination on February 17, 1941, giving the following history: For the past two years the right eye has been inflamed at intervals. The eyeball becomes red, feels sore, especially at the inner corner, waters, and discharges sticky secretion in the morning. The left eye gives no trouble except that it waters occasionally. She has never worn glasses. She has dyed her eyelashes and eyebrows over a period of at least 10 years, but has used no cream around the eyelids. She does much hair tinting and handles chemicals, but has never had any skin irritation. When the inflammation in the right eye first began, she had her family physician look at the eye and he removed some lashes from the lower eyelid. She has had no treatment except boric-acid solution, occasionally argyrol, and yellow oxide ointment, which she used when the eye was particularly inflamed. For the past three or four months she has felt a thick hardness in the lower right eyelid and friends have remarked that her lower eyelids look full.

* Read at the eightieth annual meeting of the American Ophthalmological Society at Hot Springs, Virginia, May, 1944.

Examination. O.D.: The lower eyelid looked slightly fuller than the left, but there was no congestion of the overlying skin. On palpation, a hard induration, especially in the region of the fornix, could be felt. The caruncle was slightly congested, and a small droplet of mucus was present at the inner canthus. No other discharge was evident. Along the margin of the lower eyelid on the con-

mainder of the palpebral conjunctiva appeared normal. The eyeball appeared normal, as did the semilunar fold.

O.S.: The conjunctiva of the lower lid appeared slightly pale and waxy, but the conjunctival vessels were visible and there was very little thickening of the tissue. There was no palpable induration of the lid. No discharge was present. The upper lid was normal. V.: O.D. = 20/25; O.S.

Fig. 1 (Elles). Amyloidosis of palpebral conjunctiva.*

junctival side was a slightly elevated ridge of pale, finely corrugated, waxy tissue like avascular granulation tissue. On eversion of the lower lid the conjunctival surface showed pale elevated vertically ridged tissue, much more pronounced in the nasal half of the lid, where it was elevated about 2 mm. above the tarsus. There was a tubular mass of this pale waxy tissue occupying the whole lower fornix, thicker near the inner canthus. On eversion of the upper lid a similar pale but smoother and less elevated avascular area was seen on the conjunctival surface, extending from the inner canthus about 4 mm. temporally. The re-

= 20/25. The patient was refracted and the following glasses given: O.D., +0.50D. cyl. ax. 170° = 20/20; O.S. -0.75D. sph. \approx +1.50D. cyl. ax. 170° = 20/20. The pupils reacted normally to light and convergence; the intraocular pressure was normal; the media were clear; the fundi were negative.

A smear and culture from the conjunctiva were examined and reported negative for organisms. The patient was sent for physical examination to an internist, who reported the examination negative. It was decided not to give the patient the Congo red test for fear of staining her conjunctiva, as it is known that Congo red is retained in amyloid tissue for a long period of time. A biopsy specimen was taken

* Permission was given by the patient to publish her photograph.

from the conjunctival surface of the right lower eyelid near the inner canthus and the fold in the lower fornix. The tissue bled only slightly. The specimen was sent to the Army Medical Museum for examination. An examination of the tongue, pharynx, and larynx was negative except for an elevated mass at the extreme end of the right lower jaw, some distance behind the last tooth. This had the shape of a molar tooth but was soft tissue. A piece of this tissue was also sent to the Army Medical Museum for biopsy.

The report of biopsy from Lt. Col. J. E. Ash of the Army Medical Museum was as follows: "The report from your case shows the stroma of the conjunctiva infiltrated with irregular masses of homogeneous hyaline material which with special stain seems to be amyloid. The overlying epithelium shows irregular atrophy. There is a small amount of chronic inflammatory reaction about the hyaline masses. *Diagnosis:* Amyloidosis, palpebral conjunctiva.

"Report on tissue taken from lower right jaw: Two white nodules, measuring respectively 5 by 4 by 1.5 mm. and 5.5 by 4.5 by 2 mm., the external surfaces of which are fairly smooth. The smaller mass is indurated, the larger mass apparently much less dense.

"*Microscopic:* The specimen consists largely of dense hyaline fibrous tissue and except for the unusual thickness of the covering epithelium, has the appearance of an irritation fibroma. There is no evidence of amyloidosis."

The patient was given powdered liver, 4 gm. in orange juice, three times a day. This was continued until information regarding preparation of whole fresh liver was received from Dr. H. G. Grayzel of Sea View Hospital. The patient continued taking this latter preparation for nine months. She then refused to take it any longer. Following this therapy, the right

eyelid became much softer, but the left lower fornix began to show a small fold of waxy tissue.

During this period, only a 2-percent solution of boric acid or a mild zinc sulfate and boric-acid solution were used locally in the eye. Occasionally a slight mucoid discharge was present.

On February 15, 1942, the patient was sent to the Eye Institute of Columbia University for consultation with Dr. Phillips Thygeson, especially for investigation as to the possibility of a virus infection as a causative factor.

Dr. Thygeson's report is as follows: "We were unable to find any local infection of bacterial, virus, or other nature which could account for the condition. We were unable to find any evidence of amyloid disease in any other part of the body. . . . The only abnormal finding was the occurrence in some epithelial cells over the lesion of eosinophilic bodies of uncertain nature, some resembling the inclusion bodies of virus diseases. We made chorio-allantoic membrane inoculations, but did not obtain any lesions. The inclusion bodies resemble those of certain virus diseases, but there is no way of proving their virus nature without obtaining positive animal or egg inoculation."

Further epithelial scrapings of the conjunctiva have been made at four different intervals and in none were the cytoplasmic inclusion bodies again found.

During the patient's stay at the Eye Institute, she was given a number of injections of liver extract.

Upon her return home she was given injections of 500 mg. of ascorbic acid every 48 hours for 6 doses. This was followed by 200 mg. of ascorbic acid by mouth twice a day. Some three months later as amyloid development in the left lower lid seemed to be increasing, she was given fresh liver in addition, which she

continued for three months when she again developed a marked distaste for it. At that time the therapy was changed to calcium gluconate, one drachm three times a day and 0.5 gr. of iodine, which she continued to take for four months. This did not affect the amyloid condition; so she was again given ascorbic acid, 100 mg., and vitamin A, 25,000 units,

which involves tissues of mesenchymal origin, in contradistinction to secondary amyloidosis, which involves tissue of parenchymatous origin.

Reimann, Koucky, and Eklund⁷ state that:

1. The primary form of amyloidosis is characterized by (a) absence of preceding disease; (b) no involvement of

Fig. 2 (Elles). Section of conjunctiva showing diffuse deposit of amyloid throughout section; few capillaries with ring formation of amyloid; lymphocytic infiltration; crypts lined with epithelium; some epithelial masses below due to cutting of section ($\times 50$).*

each twice daily. The amyloid process is showing some regression as there is no longer the small ridge of waxy tissue extending beyond the lid margin; the induration of the lids is much softer. Both upper lids remain normal save for the small originally involved area on the right upper lid near the inner canthus.

DISCUSSION

Amyloid degeneration may follow trachoma and other chronic infections of the conjunctiva, but authors agree that these conditions are not its cause; it may arise in eyes otherwise healthy, and so be a primary affection. Primary systemic amyloidosis is a disease of unknown cause

organs or tissue usually affected in the secondary form; (c) involvement of mesodermal tissue, cardiovascular system, gastrointestinal tract, smooth and striated muscle, and lymph nodes; (d) variation in staining reactions; and (e) tendency to nodular deposits.

2. The secondary form usually follows chronic diseases and is characterized by large deposits—especially in the spleen, liver, kidney, and adrenals—and by typical staining reactions.

3. Tumor-forming amyloidosis has been especially studied by von Bonsdorff. This form is characterized by presence of small, solitary, or multiple tumors in the eye, bladder, urethra, pharynx, tongue, and especially in the respiratory tract. It is usually of the primary type but is dis-

* Photomicrograph made at the Army Medical Museum.

inctive enough to be grouped separately.

4. Amyloidosis occurring with multiple myeloma is in a class apart. It is secondary in nature but the distribution and character of the deposits frequently resemble those of the primary form except that huge deposits may occur in the joints and elsewhere. The spleen and liver are seldom infiltrated. Small deposits are occasionally found in the blood vessels. Thirty-seven cases have been surveyed by Magnus-Levy. According to Reimann and Eklund,⁸ among the more important theories are those which claim that amyloidosis is due to: (a) a general disturbance of protein metabolism; (b) an antigen-antibody union and precipitation; (c) an absorption of protein; (d) a disturbance or abnormality of the reticulo-endothelial system; (e) hyperglobulinemia; and (f) hyperproteinemia and disturbance of the reticulo-endothelial system.

They injected rabbits with sodium caseinate three times a week over long periods and induced fatal amyloidosis. Soon after the beginning of the experiment, hyperglobulinemia developed in each rabbit, persisting until death. The total content of the blood was increased in the early period of the experiment but diminished below normal late in the course, when evidence of renal amyloidosis and uremia appeared. Their experiments support the view that chronic hyperglobulinemia is an important factor in the etiology of amyloidosis of the secondary type.

Smetana,⁹ experimenting with induction of amyloidosis in mice by injection of nutrose and blocking the reticulo-endothelial system by injections of India ink to prove that the reticulo-endothelial cells are actively concerned in the formation of amyloid, draws the following conclusions:

1. The appearance of amyloid in places

where reticulo-endothelial cells are normally present, sometimes in very large numbers.

2. The formation of early amyloid in the small solitary patches which suggest its local formation.

3. The occurrence of solitary patches of amyloid apparently located within the capillaries of the liver.

4. The manifold relations between reticulo-endothelial cells marked out by phagocytized ink granules, loose ink particles, and amyloid described in the text.

5. The impossibility of demonstrating reticulo-endothelial cells in areas of forming amyloid by intravenous injections of India ink.

6. The delayed appearance of amyloid in animals after blockage of the reticulo-endothelial cells by repeated intravenous injections of India ink.

HISTOPATHOLOGY

Sections of conjunctiva of the author's case revealed an irregular surface with coarse lobulations. With hematoxylin and eosin stain the main tissue was an almost acellular pink-staining homogeneous substance. The surface was covered by stratified epithelium, usually polyhedral in shape, with small round oval blue nuclei in which chromatin was very fine. Occasional epithelial cells were vacuolated with the nucleus crowded to one side, giving a signet-ring appearance suggesting the presence of mucous secretion in the cells. The surface layer of epithelium varied from 1 to about 10 cells in thickness. A few crypts were seen on cross section, presenting a glandular appearance. Surrounding a few of these were a moderate number of lymphocytes. A small amount of exudate was present on the surface in one place, chiefly fibrin, polymorphonuclear neutrophils along with occasional plasma cells, eosinophils, and desquamated cells.

Beneath the surface there were very few nuclei, and the material was largely structureless. A few connective-tissue cells with slender nuclei and long processes were present. What appeared to be capillaries were sparse and small, although one or two had a large lumen. No blood was present in these. The lining

thelium and connective tissue were a very distinct blue. Congo red gave the homogeneous material a strong orange-red color, whereas iodine stained it mahogany brown. The latter stain faded rapidly. Tissue submitted to the Army Medical Museum was reported by Lt. Col. Ash to give a positive iodine stain.

Fig. 3 (Elles). Section of conjunctiva. Note altered surface epithelium; abundant structureless material (amyloid); few connective-tissue cells; capillaries with swollen endothelium ($\times 260$).*

endothelium appeared swollen. A few capillaries were surrounded by a layer of pink material giving a ringlike appearance. The greater number were free from this ringlike deposit. The homogeneous material appeared in coarse irregular lobules separated usually by thick strands of elongated cells of connective tissue and was moderately dense. Selective staining by crystal violet, Congo red, and iodine gave the staining reaction of amyloid. Crystal violet stained the material dark reddish purple, whereas the surface epi-

Duke-Elder⁶ states that

Pathologically, the changes originate in the subconjunctival cellular tissue which suffers a massive cellular infiltration of plasma cells, leucocytes, mast cells, and wandering cells—of these the plasma cells are greatly predominant (Kubik, 1924). The earliest signs of degenerative material—amyloid or hyaline—are in the neighborhood of the small vessels (Wallgreen and Vannas, 1926). The commencement of the changes is in the connective-tissue fibers of the middle coat of the smaller arteries, which, with their subsequent enormous swelling so that the lumen may be obliterated, and the spread to the formed tissue elements with the destruction of the parenchymatous cells, have already been described. . . . The epithelium is thinned and may undergo cornification. Finally other degenerative changes may supervene: fatty in-

* Photomicrograph was made at the Army Medical Museum.

filtration (Vollaro, 1913), glycogenous infiltration (Schieck, 1908), or calcification (Vossius, 1889); Marchi, 1908; Rumschewitsch, 1909; Kolominsky, 1912).

Leo¹⁰ in a case of amyloid disease following trachoma, gave the following description of biopsy findings over a period of four years.

In 1935, the tissue showed homogeneous masses traversed by bundles of connective tissue, chronic inflammatory processes consisting of lymphocytic infiltration and plasma cells, with prevalence of the former grouped especially around the small blood vessels and many blood vessels with thickened walls. The vessels showed endothelium but were constricted. Only certain portions took specific amyloid stain, whereas the hyaline substance took the stain more generally.

In 1936, the tissue removed showed intense amyloid degeneration. It consisted entirely of a mass of amorphous material which stains irregularly. It still showed few areas of homogeneous structure which could be stained as hyaline substance. Thin remains of conjunctiva and some small blood vessels could be seen. There was no inflammatory process in evidence.

In 1938, epithelium of the tarsal conjunctiva consisted of flat lamellar cells. The subepithelium showed a wide stratum of cells, having no particular arrangement; in some places there was a reticular arrangement of connective tissue of hyaline character but no formation of follicles as in the common form of trachoma. There were many blood vessels with thickened walls and restricted lumina. The fibrosis increased and lymphocytes were scarcer; there was a progressive increase in connective-tissue bundles with hyaline characteristics. These bundles were followed by masses of amyloid substance around the blood vessels and formed compact masses. In the middle of these masses were found small calcified areas.

As the process advanced, the inflammatory process showed more and more degenerative character. Following this was a phase of hyaline sclerosis, and later a phase of amyloid degeneration. In the second biopsy the inflammatory process had ceded to an amyloid degenerative process. In the third biopsy both processes were still going on and there was still the infiltration of trachoma.

Leo agreed with the observation of Kubik (1882) and Del Monte (1910) that there are four phases of degenerative change in evolution of the process:

1. Inflammation—cellular infiltration (plasma cells which can be absent).
2. Hyaline degeneration.
3. Amyloid degeneration.
4. Calcification.

He quoted Von Gierke as saying that amyloid prefers cartilagenous tissue or tissues rich in elastic fibers and so the palpebrae show this degeneration.

Adrogué¹¹ said the mechanism of the amyloid degeneration excluded any direct intervention by the plasma cells, claiming that this direct intervention was due to the absorption of the amino acids by the collagens of the interstitial network as a consequence of the bad condition of the nutritional balance which impeded elimination through the natural channels. The transformation of the plasma cells into hyaline substance is a fact that has been proved by Unna and also by Ishihara (in the conjunctiva).

Rybnikova,¹² in argument for the support of the theory that amyloid localizes along the reticulo-endothelial system, drew attention to the fact that the process begins in the tunica adventitia of the blood vessels where the largest accumulation of reticulo-endothelial cells are. A study of her case of amyloid disease of the conjunctiva gave reason to suspect that toxins first produce irritation, then depression, beginning with the tunica adventitia. In some instances the walls of the vessels showed definite marks of irritation which could be demonstrated by a very active proliferation of the cellular elements of the tunica adventitia; in others only the remnants of previously existing proliferation could be seen.

Furthermore, it may be possible that the existence of chronic toxemia (be it trachoma or other irritant) produced partial blockade of the reticulo-endothelium; its functions were decreased and finally ceased. Since reticulo-endothelium is the principal regulator of protein

metabolism, conditions may arise causing a change in local chemical process of tissue so that normal proteins brought by the blood may assume a new chemical structure in the form of amyloid.

BIOCHEMISTRY

Hirschfeld, in 1882, was apparently the first to produce amyloidosis in the experimental animal. This was repeated and confirmed by Jaffe. Rokitsansky, as far back as 1885, formulated the concept that the presence of amyloid substance is due to infiltration or deposit of an abnormal substance from the blood stream into the reticulo-endothelial system. Pearlman¹⁴ says the nature of amyloid substance has remained a matter of considerable controversy. The most widely accepted view is that expounded by Krakow, who, in 1897, described amyloid as a combination of protein with chondroitin-sulfuric acid. Perla and Gross¹⁴ reported that this was contradicted by Hanssen, who found no chondroitin-sulfuric acid. Eppinger found purines, diamino-acids, much tyrosine, and no carbohydrates.

Grayzel¹⁵ and his co-workers believe that amyloidosis is probably the result of an endogenous protein metabolic disturbance. When the rate of formation of these catabolic products exceeds the ability of the tissues to dispose of them, amyloid appears. Amyloid deposition has been produced experimentally in several animal species by repeated injection of bacteria, sterile bacterial toxins, and non-toxic proteins. Among the bacteria, staphylococci seem to be the organisms of choice for the experimental production of amyloidosis. Among the toxins, diphtheria toxin is very effective, as has been repeatedly shown by the frequent occurrence of amyloid disease in horses used for the production of antitoxin. Relatively nontoxic material such as sodium caseinate, horse serum, and human serum will

produce amyloid disease in mice if the materials are repeatedly injected over a period of several weeks. Amyloid frequently appears in the organs of mice which have spontaneous or experimentally induced tumors. Some investigators have claimed that amyloid disease will develop in mice maintained on a diet of nutrose or sodium caseinate. Turpentine with production of sterile abscess may call forth amyloid reaction. It would seem likely that under certain conditions a fundamental disturbance in protein metabolism may occur which results in this abnormal deposition of an unusual protein. It would be interesting to investigate whether the diet plays any role in such a disturbance in human beings.

Letterer¹⁶ suggests in primary amyloidosis the involvement of an antigen-antibody reaction, but in the reverse sense as compared with the reaction presumed to exist in the secondary form of amyloidosis. Fowler¹⁷ believes that amyloid is apparently a transformation product of tissue protein which is deposited in soluble form. It is always extracellular and is transported to the organ or tissue rather than synthesized *in situ*. Composition of the material has not been accurately determined, though it is known that starch and cellulose, from which the term amyloid is derived, are not present. Reimann and Eklund⁸ found that hyperproteinemia precedes amyloid deposit in animals, and they consider this the abnormal substance in the blood stream. The lack of unlimited power of the organism to dispose of nonutilizable split protein products is compensated for to a certain extent by the phagocytic power of the reticulo-endothelial system. Eventually a point is reached, however, where this system can no longer undergo hypertrophy and hyperplasia, and decompensation of phagocytosis occurs. Increasing masses of material accumulate intra-

cellularly and finally the cells burst to form extracellular deposits. While hyperproteinemia and the reticulo-endothelial system undoubtedly play a role in the production of amyloidosis, it is not clear whether the hyperproteinemia is a primary factor or merely mirrors a more fundamental process.

Hass and Schulz¹⁸ undertook to test the hypothesis of Letterer that amyloidosis is due to an antigen-antibody reaction by attempting to isolate the antibody protein from the amyloid matrix. Unfortunately, there is no satisfactory method for dissociating specific precipitates composed of protein antibody. For this reason, it is improbable that the two proteins they obtained in their experiments represent unimpaired dissociated antigen-antibody. They isolated three types of amyloid which in spite of their differences in composition disappeared from the tissues in phosphate buffer solutions at pH 11 and remained in the tissues in phosphate buffer solutions at pH 10. As amyloid disappeared from the tissues two proteins appeared in the solvent. One protein (A) comprised about 90 percent of the total protein. The second protein (B), which was always present in small amounts, had different properties. Inasmuch as fraction B was incapable of combining with fraction A to form an insoluble precipitate at neutrality, and inasmuch as they believed that amyloid is a precipitate which forms a physiologic neutrality in the tissues, an unknown component which acts on fraction A *in vivo* in a way comparable with that of acetic acid *in vitro* is a desirable part of the model.

Rybnikova¹² tells of an interesting theory by Wichmann, which represents the process of amyloid formation in the following manner: Owing to the toxic disturbance of the cellular metabolism the function of the cells is impaired to such

an extent that they are unable to assimilate the albumin brought by the blood. This surplus of albumin is deposited in the interstices, and there under the influence of some ferment secreted by the cells or some other unknown cause is transformed into amyloid.

Grayzel¹⁵ and his co-workers, in experimenting on mice, found that inadequate or deficient diets do not accelerate the development of amyloidosis. Mice fed a synthetic and the so-called stock diet to which vitamins A and B were added showed definite evidence of retardation of the production and formation of amyloidosis.

DIFFERENTIAL DIAGNOSIS

Amyloid disease may involve not only palpebral conjunctiva, but also the bulbar conjunctiva and the cornea. The process may be diffuse, or may assume the aspect of a well-delineated tumor. It is to be differentiated from hyalinization of the eyelid, tarsitis syphilitica, fatty degeneration, as well as various neoplasms, benign or malignant, diffuse lymphoma, plasmoma, scleroma, lymph- and hemangioma, and forms of sarcoma. Only histopathologic examination of the tissue determines the real nature of the disease.

Intravenous injection of Congo red is the specific test for the presence of amyloid. This simple clinical method for the diagnosis of amyloidosis was first described by Bennhold, in 1923. Among normal persons, 19 percent of the dye disappeared from the blood stream in one hour after injection, whereas among patients with amyloidosis 40 to 100 percent of the dye was found to have disappeared. This observation has been confirmed by many observers. Waldenström¹⁹ was able to take specimens from the liver for biopsy with a specially made trocar, and by this method he was able to follow the development, reabsorption, and complete disappearance of the dye in the liver.

Friedman and Auerbach²⁰ have recently published an improved method of Congo-red injection for diagnostic testing. One might hesitate to use it in a case of conjunctival involvement, because of the prolonged retention of the dye in amyloid tissue, unless surgical removal of the involved tissues is contemplated.

Hyaline degeneration has been considered by several observers—Kubik,²¹ Ernyei,²² Leo²⁰—as an early stage of amyloidosis.

Kreibitz²³ stated that there was no connection between amyloidosis and plasmocytoma as these diseases are due to entirely different reactions of the organ. There are no well-defined cases in which both of these conditions appeared simultaneously. Trachoma was almost always present in plasmocytoma, and relatively few cases of trachoma developed amyloidosis.

TREATMENT

Excision of the tissue involved in amyloid disease of the conjunctiva, either entirely or in part, is the method of treatment universally advised in the reports published in various countries. At times where the denuded area is extensive, grafts of mucous membrane from the mouth have been successfully applied. Many authors report that total ablation is not necessary, as they have found the remaining amyloid tissue undergoes retrogression.

The reports in general medical literature of amyloid disease being cured (especially in tubercular patients by prolonged administration of liver, powdered or fresh), a case of cure with only symptomatic treatment reported by Halbein,²⁴ and Waldenström's¹⁹ report of his ability to show that complete disappearance of amyloid is possible in man despite extensive infiltration of the liver, influenced me to treat my patient on the theory

that amyloid formation in the conjunctiva is a deficiency rather than a degenerative disease.

According to Dalldorf,²⁵ ascorbic acid is an essential nutrient required for the normal deposition and maintenance of intercellular substances. This includes the collagen of all fibrous tissues and of all nonepithelial cement substances (the intracellular material of the capillary wall, cartilage, dentin, and bone matrices).

During vitamin-A deficiency the Kupfer cells become swollen and degenerate. It is quite possible that a part of the effect of vitamin-A deficiency on infectious diseases is due to this involvement of the reticulo-endothelial system (Eddy and Dalldorf²⁶).

The patient cited in this paper has been given fresh liver over a period of many months, followed by vitamin C and later by vitamins C and A, with a resultant slow regression of the disease.

CONCLUSIONS

Amyloidosis may manifest itself in the conjunctiva as a primary and, perhaps, as a secondary disease. The fact that most cases reported have followed or complicated trachoma need not necessarily mean that the trachoma is a factor in the development of amyloid, for the majority of trachoma cases do not develop amyloidosis. The geographic location of most cases of eye involvement—that is, the Baltic states, Russia, Japan, and China, where deficiency diseases are more prevalent—would indicate that this might be a factor.

There is no single pathologic criterion upon which a diagnosis of primary amyloidosis can be made. The absence of preceding suppurative disease; the lack of evidence of amyloidosis in the internal organs commonly involved; the presence of amyloid in smooth or striated muscles, especially in the cardiovascular system,

gastrointestinal and genito-urinary tracts, tongue, more rarely in the alveoli of the lungs, and the sebaceous and sweat glands—all sites of primary amyloidosis; the atypical staining reactions to Congo red and iodine sulfuric acid; and the nodule formation that is found in conjunctival cases are at present the only bases for diagnosing the primary form.

Biochemically, the process of amyloid deposit appears to be a disturbance in protein metabolism, due not to transudation of a protein substance formed in the blood stream, but to an endogenous protein metabolic disturbance, in which the rate of formation of catabolic products exceeds the ability of the tissues to dispose of them.

Histopathologically, most evidence points to primary involvement of the phagocytic reticulo-endothelial cells, whose location is exactly in the places where amyloid is constantly seen. The

changes begin in the connective tissue of the tunica adventitia of the smaller arteries.

The Congo-red test is diagnostic, but should not be given in cases of eye involvement because of the retention of the stain in the tissues, unless surgery is to be done immediately. Iodine, Congo red, and crystal violet stains give characteristic coloring to amyloid material.

The only treatment of eye cases reported is surgical removal of the amyloid diseased tissue.

Definite, but slow, regression of the amyloid process in the author's case treated first by ingestion of fresh liver, later by vitamins A and C, would suggest the disease is due to a deficiency.

It might be desirable to abandon the term degeneration entirely in regard to amyloid formation in the tissues and to refer to the condition as amyloid disease.

CLINICAL EFFECTS OF THE LOCAL USE OF SULFONAMIDES ON THE EYES

. MOACYR E. ALVARO, M.D.
São Paulo, Brazil

The local use of sulfonamides for the treatment of pathologic ocular conditions is based on the fact that these drugs are relatively innocuous when they come in contact with the ocular tissues, as was demonstrated in *anima vili* (rabbits) in 1938 by Rambo²⁵ and clinically proved later by many other authors;¹⁶ it was also proved that sulfanilamide readily penetrates into the ocular globe with topical use, as do sulfapyridine and sulfathiazole; also sulfadiazine when iontophoresis is used or when an agent capable of breaking superficial tension is employed beforehand. Any of the four sulfonamides mentioned above are efficacious in the treatment of pathologic conditions of the conjunctiva and cornea, whether they are used in powder or ointment form. Local use of azosulfonamides, however, is not plainly justified, for this drug is transformed into sulfanilamide only within the human organ-

ism, and the favorable clinical results that have been reported should merely be compared with those obtained by the use of ordinary nonirritating collyria (Bellows⁵). Another considerable advantage of the therapeutic use of sulfonamides by local application is that the quantity of the drug entering the organism is practically negligible, the desired concentration being obtained only in the affected region, this being much greater than any concentration obtainable by any other means of administration; moreover, the time spent in obtaining the desired concentration is very much reduced.

According to Thygeson⁴³ it seems probable that the topical use of sulfonamides in ocular therapeutics will largely supplant the oral administration, because in the future it will be possible to use drugs with a highly active local effect, the toxicity of such drugs making their

use unadvisable *per os* or parenterally.

The local use of the sulfonamides in ocular therapeutics, however, was not accepted at once. Some years after the oral and even parenteral use of these drugs had been accepted in the treatment of ocular diseases, references to their local use were rare. This may be explained by the fact that the sulfonamides are only slightly soluble in water, which is the base ordinarily used for collyria. Sulfanilamide reaches its maximum concentration at less than 1 percent (0.8 percent) and at this concentration the collyria were not really very efficacious when instilled, ocular baths giving better results (Mengel²⁴). It was necessary to resort to insufflation of the drug in powdered form (P'an²⁰), but since this was not well tolerated, administration in this form was really impractical. Subconjunctival administration was then tried (Paton³¹); later came the ointments, the preparation of which at first did not give satisfactory results. These were followed by sodium salts of the various sulfas, their solubility in water being much greater; but a high pH was needed, making the collyria in question irritating. This step was followed by local administration with iontophoresis, which allows a rapid penetration of large quantities of sulfa into the ocular tissues. Although the prior use of agents capable of breaking the superficial tension of the cornea is still in its experimental stage, it promises to open up new means of the local application of the sulfas in the treatment of ocular diseases.

ACTION OF THE SULFONAMIDES APPLIED DIRECTLY TO THE OCULAR TISSUES

The action of sulfonamides is known to be bacteriostatic and not truly bactericidal. On accepting the hypothesis that the sulfas act by affecting the para-aminobenzoic acid, one must take into consideration, in their local therapeutic use, that

the anesthetizing collyria have structural formulas similar to the structure of that acid and that therefore their simultaneous use with the sulfas will hinder their respective action. In the same way and according to the same theory the existence of abundant secretion might also hinder the local action of the sulfas.

One might think that the sulfonamides would have an inhibiting effect on the phagocytic action of the white blood corpuscles. Experiments carried out on animals, outside the field of ophthalmology, demonstrate the opposite: among rats inoculated with agents of gas gangrene, phagocytosis was greater in those that had been given sulfonamides locally in the wounds.³⁰

However, experiments carried out by Bellows⁴ show that corneal reepithelization in rabbits took, on an average, 5.1 days, whereas in rabbits treated locally with sulfonamides the period of epithelization was 13.6 days.

Berens, Gara, and Loutfallah's⁶ observations agree with those of Bellows, the former authors having found that the period of cicatrization of corneal wounds in rabbits treated with ointments with or without sulfonamides was longer than in those which received no treatment. These authors also found that when the wounds were infected with *Staphylococcus aureus*, the percentage of cures was greater in the eyes treated with 5-percent sulfa ointment.

Bellows⁴ states that local application of sulfonamides to the cornea not only retards cicatrization but causes the formation of vascularized scars.

The clinical inference from these facts is that the sulfonamides should be applied locally to corneal wounds only when there is suspicion of infection. Conversely, according to personal observations in clinical practice, the aforementioned experiments can be confirmed, for in infected

ulcers of the cornea the use of sulfonamides should be suspended when the ulcer by its aspect shows that it is regressing, so that by continuation of treatment the drug will not retard cicatrization.

METHODS USED IN LOCAL SULFONAMIDOTHERAPY

The sulfonamides used topically in ophthalmologic therapeutics are sulfanilamide, sulfathiazole, and sulfadiazine, sulfapyridine being used much less frequently. Sulfanilamide is soluble in water up to 0.8 percent and this aqueous solution has been used. Sulfathiazole and sulfadiazine are less soluble in water and for aqueous collyria their sodium salts are employed. Sodium sulfacetamide, from which solutions up to 30 percent can be obtained, has been widely used for topical applications in ophthalmology (Pillat³²). Tolerance of these collyria is good; generally there are no irritative phenomena. It is advisable that they should be isotonic. The collyria may be instilled frequently at short intervals (every 5 seconds, 60 times) or used as an ocular bath for 3 to 5 minutes, repeated every 2 hours. Liquid collyria of sulfonamides may also be used for irrigations of the conjunctival cul-de-sac, these irrigations being repeated more or less frequently according to the case, at intervals of from 15 minutes upward between irrigations (Rein and Tibbetts³⁷). Pure sulfonamides can be used by insufflation, dusting or insufflators being used for this means of administration.¹³ Insufflations are generally given every three hours. This method of application is useful for patients in hospital, but is difficult for use with out-patients.

It is necessary to keep in mind that due to the mode of action of the sulfonamides in inhibiting the development of the germs, without, however, destroying them directly, a continuous local action is in-

dispensable, so that instillations should be repeated frequently, and insufflations should be given so that there will always be a reserve quantity of sulfonamides to be dissolved by the tears.

Sulfonamides when administered by insufflation, however, do not seem to be completely innocuous, and irritative phenomena resulting from this method of using the drug have been reported (Guyton and Woods¹⁵). Bellows⁴ also verified the appearance of chemosis and coloration of the corneal epithelium after application of powdered sulfonamide for two hours. Sulfanilamide and sulfadiazine seem to be better tolerated in local application than is sulfathiazole. In any case it is always preferable to porphyryze the drug or to use the microcrystals. (Thygeson,⁴³ Leopold and Scheie²).

Ointments present several advantages over the collyria in the local application of the sulfonamides to the lids, conjunctival cul-de-sac, and cornea, because as the sulfonamides are but slightly soluble in water, aqueous collyria of their sodium derivatives, which are sometimes irritating due to their alkalinity, are generally used, whereas in the ointments pure sulfonamides can be employed. Besides this the ointments are generally well tolerated by the patients, whose only complaint is the disturbance of visual acuity caused by the extremely thin layer of unctuous substance that forms on the cornea. Emulsions, according to Thygeson and Bralley,⁴⁴ are advantageous in that the drug is released more rapidly, but their drying properties make them irritating when used on the lids. Ointments also allow for a more prolonged action of the drug. Thygeson and Bralley found that the base which kept its drug-diffusing property the longest was hydrous wool fat; evident traces of the drug were present in the cornea of rabbits 60 minutes after only one application of 5-percent sulfa-

thiazole ointment in this base. This finding demonstrates that with an adequate base, ointments can be used less frequently than the aqueous collyria and yet have a similar effect.

Ointments must have certain requisites to make their administration effective, these requisites varying according to whether the ointment is to be used on the skin or conjunctiva. Therefore, according to Pillsbury, Wammock, Livingston, and Nichols³³ ointments for use on the skin of the lids should retain the drug in a finely divided state at the site of application for the longest possible time period; (2) allow close contact of the sulfa with the site of infection; (3) be miscible with mucous and purulent secretion; (4) not form a tight waterproof layer under which bacteria could develop; (5) allow for easy removal of the bacteria found in the crusts. These authors found that purely fatty bases such as petrolatum, hydrous wool fat, and the like, all have the requisites required by item 1 but do not meet the demands for the other items; they state that they prefer an emulsion in which the sulfonamide is first dissolved or kept in suspension in water, this suspension or solution being afterward emulsified with the greasy base. These emulsions permit a more intimate contact between the drug and the affected part, they mix with secretions and, owing to the lessened superficial tension, a better release of the drug to the tissues is obtained. For the conjunctival cul-de-sac the use of a hydrous-wool-fat base seems to be preferable. Elvin¹² recommends the following formula: To 4 parts of sodium alginate add 75 parts of boiling water; emulsify and strain, and then stir until cool. Add 16 parts of anhydrous wool fat, 78 parts of white petrolatum, and 1 part of sodium chloride dissolved in 4 parts of water. This base was found to be the best for the use of sulfanilamide or sulfathiazole.

The breaking of superficial tension beforehand by the use of detergent preparations permits a far greater penetration through the cornea and aqueous when sulfonamides are applied locally. Detergent preparations are understood to contain the necessary ingredients for lowering superficial tension, thus permitting an increase in penetration. These preparations consist of molecules containing polar and nonpolar groups. As a result these molecules are concentrated on the surface of the cornea and orient themselves so that the polar group comes in contact with the epithelium and the nonpolar portion is directed to the surrounding media. Consequently interfacial tension between the surrounding media and the epithelium is reduced, causing increased penetration not only of the detergent but also of the surrounding elements. It is known that one of the reasons of the difficulty for the penetration of the sulfas into the cornea is due to their polar nature (Swan and White⁴²). Therefore a previous application to the cornea of a preparation capable of reducing superficial tension would logically increase penetration of the sulfas.

In 1942, Alvaro and Silva,¹ assisted by Prof. Q. Mingoja for the chemical part (in a paper presented before the Section of Ophthalmology of the American Medical Association) demonstrated that after instillation of 1 drop of a 15-percent aqueous solution of sulfacetamide 60 times in succession at 5-second intervals into rabbit eyes, a concentration of 2.23 mg. of sulfa per 100 c.c. was obtained in the aqueous after half an hour. However, if a drop of dioctylsulfosuccinate was instilled previously and the same experiment repeated, the concentration in the aqueous rose to 8.68 mg. per 100 c.c. Bellos and Gutman,³ also experimenting with rabbits and using various preparations to lower superficial tension, such as dioctylsulfosuccinate (known by the com-

mercial name of "Aerosol OT"), isopropyl-naphthelene sodium sulfonate ("Aerosol OS"), higher secondary alcohol sulfate ("Tergital 4.7"), synthetic primary alcohol sulfate ("Tergital 0.8"), oleyl alcohol ("Ocenol KD"), high-molecular alkyl, dimethyl and benzyl ammonium chlorides ("Zephiran"), were able to increase the penetration of sulfathiazole in the aqueous in similar proportions. Zephiran was the only agent with which results were not so satisfactory. These authors verified that with 0.2-percent detergent solutions ("Aerosol OS") they were able to obtain an increase in penetration of the sulfa in the aqueous and with 10-percent solutions saturation was attained. Solutions of these detergents of less than 2 percent do not seem to harm the cornea, and this leaves a wide-margin of safety if detergent solutions of 0.3 to 0.5 percent are used, for their effect on the increase of penetration is already great.

The existence of vasodilatation and inflammatory conditions of the cornea facilitates corneal penetration, as does also application of local heat for the same reasons.

Owing to the fact that sulfonamides penetrate into the aqueous in large quantities when administered subconjunctivally, their clinical use by this method was established. Paton³¹ employed subconjunctival injections of neoprontosil in 0.2 to 0.3 c.c., using 2.5- and 5-percent solutions. Good results were obtained and local inflammatory reaction was not very great. This method of administering the sulfonamides locally in ocular therapeutics has not been generally favored owing to the fact that similar or even better results can be obtained by the use of iontophoresis without the inconveniences of subconjunctival injection.

Leduc, in 1900, suggested making chemical agents penetrate into the human

organism by means of an electric current. Application of this method to the visual apparatus seems to have been done by Wirtz in 1908, but it was Cantonnet who, in 1927, reviewing the literature on the subject and adding his own theories, established this therapeutic method in ophthalmology.

The passage of the galvanic current to the cornea, whether by application of the negative pole or of the positive pole, causes a decrease of tension in the globe, which has been verified by Myerson and Thau.²⁸ This decrease is more pronounced when the negative pole is applied to the cornea, is independent of the application of chemically active agents, and takes place even when distilled water is used. Myerson and Thau explain this decrease in tension as the result of a vasodilatation or some more complex chemical action. In any case the passage of the galvanic current stimulates the parasympathetic system, as can be seen by the contraction of the pupil and narrowing of the palpebral fissure.

In iontophoresis with sulfonamides the negative pole is applied to the cornea and the positive pole to the nape of the neck. We have found in a series of patients undergoing iontophoresis for various reasons that there is invariably a decrease in ocular tension, very variable, however, for each individual and even in the same individual from day to day. This decrease was from 10 mm. Hg to 1 or 2 mm.

For iontophoresis small glass cups with a metallic electrode at the bottom may be used. The patient, with his head down, submerges the cornea in the liquid contained in the cup; or a glass tube open at the ends may be applied to the limbus, filled with an adequate solution and an electrode dipped into the liquid; or a cotton-wool pledget soaked in the solution may be placed on a metal disc connected with the negative pole of the ap-

paratus, the wet cotton wool being made to come into direct contact with the cornea. With this last method it is generally necessary to anesthetize the cornea, which, as we have seen, is inconvenient, and also there is a danger of trauma.

In order to combine the action of the drug which penetrates into the tissues by means of the galvanic current and the mechanical action of massage, we have used an adequate electrode covered with gauze and soaked in the solution indicated. With this we massage the palpebral conjunctiva in cases wherein such massage is necessary, as will be seen further on.

The current used is 1 to 2 Ma. With 1 Ma. Boyd⁷ found that penetration of sulfathiazole in a 5-percent solution in the cornea and aqueous was three times greater than that obtained with an ordinary ocular bath of equal duration. With 2 Ma. increase of penetration was 9 times greater in the aqueous and 10 times greater in the cornea. The increase of the concentration of the sulfonamide solution determined an increase in concentration of the drug in the tissues, which, however, was not proportional to that increase. Boyd⁷ found no corneal lesion caused by iontophoresis with sulfathiazole solution.

Von Sallmann,⁴⁸ experimenting with rabbits, found that the penetration of sulfadiazine by iontophoresis was even greater than that obtained by Boyd with sulfathiazole; penetration of sulfacetamide and sulfapyridine, however, was less. Von Sallmann also found that the penetration of the drug is very rapid, reaching a maximum concentration in 15 minutes, remaining in all the tissues and liquids of the anterior segment of the globe for four hours in a bacteriostatic condition.

For iontophoresis we have regularly been using solutions of sodium sulfacetamide or sodium salts of sulfanilamide in

strengths of 5, 10, and 15 percent in various cases. The clinical results observed, which are given further on, justify our belief in the effective penetration of the drug by this method of administration. Serious irritative phenomena were not observed, these applications being well tolerated by the patients. We use a 2-Ma. current and the application is of 2 to 5 minutes' duration, according to the case.

There are other methods of applying sulfonamides locally to the visual apparatus, but their use is less generalized. Igersheimer¹⁷ refers to a case of traumatic purulent iridocyclitis with indication for enucleation due to the pronounced irritative phenomena and slight perception of light, in which, besides the classical therapy with heteroprotein, he injected a solution of 0.8-percent sulfanilamide into the anterior chamber. Inflammation disappeared, and a final visual result of 20/40 was obtained after iridectomy and extraction of cataract had been performed. Laval,²⁰ encouraged by this case history of Igersheimer, presents a case of a patient operated on for cataract in which, due to vomiting, gastric liquid entered the conjunctival cul-de-sac of an eye wherein the anterior chamber was open; in order to avoid possible infection, an irrigation of the anterior chamber with a 10-percent solution of sodium sulfadiazine was performed. No irritative phenomena of any kind were observed. Puga³⁴ also refers to excellent results in a case of abscess of the vitreous in which he substituted 0.6 c.c. of vitreous with an injectable solution of prontosil rubrum. In another case of recurrent uveitis with cataract the inflammatory phenomena ceased after intravitreous injections of the same drug.

Lavage of the lacrimal sac with sulfonamide solutions has also been used. Leopold and Scheie refer to having used a 5-percent aqueous suspension of sulfathiazole and sulfapyridine with microcrystals,

without causing irritation and with good therapeutic results. Puga³⁴ also mentions having done the same with neoprontosil.

Local administration of the sulfonamides does not exclude the oral or parenteral use of the drug. Its use may be supplementary, taking advantage of the rapidity of penetration of the sulfas into the eye, when the application is local, in order to obtain an immediate bacteriostatic effect whilst waiting for the drug administered by mouth or parenterally to reach the concentration necessary to produce a therapeutic effect after a few hours. When the sulfonamides are used orally or parenterally and locally it is not necessary to consider the quantity of the drug absorbed locally, for even if a maximum penetration is obtained there is no danger of a toxic effect.

It has been found, and we have already referred to the fact, that an increase in the body temperature favors absorption of the sulfonamides and also their bacteriostatic action; there is, therefore, no reason to contraindicate the simultaneous use of therapeutic agents which cause an increase in temperature and of sulfonamides; rather, simultaneous administration of foreign proteins, vaccines, toxoids, and the like, with the sulfas should always be indicated when necessary.

According to Thygeson⁴³ studies by Schmelkes and Wise⁴⁰ show that azochloramide and oxidizing agents increase the bacteriostatic power of the sulfonamides, so that something can be hoped for from this source, although so far clinical experiments are lacking.

With the local use of the sulfonamides no phenomena of general poisoning need be feared, for the quantities of the drug absorbed are truly very small. There are cases, however, in which patients with a great sensitivity to the sulfas showed local allergic manifestations when collyria or ointments containing sulfonamides are

applied. Howard Morrison²⁶ refers to a case of allergic blepharoconjunctivitis due to the use of an ointment of sodium sulfathiazole. When the use of the drug was suspended the symptoms of irritation disappeared, but reappeared in one eye only in which ointment had again been applied, this time of sulfathiazole. Thygeson and Braley⁴⁴ also describe several cases of conjunctival inflammation with dermatitis of the lids, pruritus, and conjunctival eosinophilia. They also observed similar cases when sulfanilamide, never when sulfadiazine, was applied locally. Personally I have observed several cases of allergic irritation caused by the local use of sulfonamide collyria and ointments, specifically with the use of sodium sulfacetamide and sulfanilamide, whether in the form of aqueous collyria or ointment to be applied in the conjunctival cul-de-sac and on the skin of the lids. All authors are unanimous in stating that with suspension of the local use of the drug, inflammatory symptoms rapidly disappear, leaving no permanent damage.

THERAPEUTIC INDICATIONS

As the sulfonamides may frequently cause toxic manifestations of a certain seriousness, their use *per os* or parenterally or intravenously should not be prescribed without due reason. Owing to the facility with which penetration of the drug is obtained locally, this method is indicated as the method of choice when the desired effects can thereby be obtained. There are cases, however, in which paradoxically results are not so encouraging with local as with oral methods.

DISEASES CAUSED BY VIRUS

Regarding ocular virus diseases, local treatment with the sulfonamides is limited to granular conjunctivitis and inclusion conjunctivitis. In the latter this is the

treatment of choice,⁴⁵ good results having been obtained especially in children. Generally, 5-percent sulfathiazole ointment in the conjunctival cul-de-sac 6 times a day is used.

Since the sulfonamides were found to be of great value in the treatment of trachoma,¹⁰ several authors have sought to obtain good results with local application of the drug. Amaral² in 1939 states that he obtained good results with massage of the palpebral conjunctiva of trachomatous patients with a 2-percent sulfanilamide ointment. Cosgrove,¹¹ in 1940, also mentions good results in a series of patients undergoing treatment consisting of the instillation of an 0.8-percent sulfanilamide solution 4 to 6 times a day. Results were equivalent to those obtained in another series treated with sulfa orally. Subconjunctival injections of neoprontosil⁸ have also been used with good results, according to Paton³¹; Morante²⁵ has used insufflations and massage with powdered sulfanilamide. Victoria and Artigas have used a collyrium of sulfathiazole (see Sená⁴¹). The majority of authors, however, advise the use of collyria of sulfanilamide, but the number of enthusiasts for the local treatment of trachoma with the sulfonamides is relatively small, treatment by mouth being advocated as a rule.

Personally, and in the Eye Clinic of the Escola Paulista de Medicina, we usually associate the administration *per os* of the sulfonamides with local treatment with collyria containing 15-percent sodium sulfacetamide. This treatment is given for 2 to 3 weeks until regression of the inflammatory phenomena is observed, then treatment *per os* is suspended, and massage with an electrode soaked in a 5-percent solution of sulfacetamide with a galvanic current of 2 Ma. is instituted. These massages aim at destroying the follicles and at the same time guarantee

a sufficient concentration of sulfonamide in the affected tissues. Ionization massage is given for 2 to 3 minutes and repeated daily. Series of 20 massages are given at intervals of 10 days, and at the end of each series the patients are reexamined in order to see whether treatment should be continued or not. Results are generally very good, the active signs of trachomatous infection disappearing together with the follicles.

It is obvious that at least a partial substitution of the general treatment by local treatment would be of great advantage, as this would permit a much more universal use of the sulfonamides in the treatment of trachoma.

DISEASES CAUSED BY BACTERIAL INFECTION

Gonococcic conjunctivitis, which has been effectively treated by sulfonamides administered orally, has also been treated locally by some authors. Mullen²⁷ used washes of a 0.2-percent solution of sulfathiazole repeated every 10 minutes. Rein and Tibbetts³⁷ used irrigations of a solution of sulfanilamide with very good results, and Panneton,³⁰ using powdered sulfanilamide, also obtained very good results. The seriousness of this ocular disease, however, seems to justify running the risk of using the sulfonamides *per os*, and perhaps it would be wiser to advocate a mixed treatment in cases of gonococcic conjunctivitis, as with this method the doses of sulfa taken orally can be reduced sooner. Sulfadiazine seems to be the sulfonamide of choice for local application in these cases (Thygeson⁴³).

Pillat³² successfully used a 10-percent collyrium of sodium sulfacetamide at 30-minute intervals in gonococcic conjunctivitis of the newborn.

I have used instillations of a collyrium of this same drug in a 15-percent isotonic solution, instilling one drop at half-hour.

intervals, with very good results. Once a day the same solution is instilled 60 times at 5-second intervals, this guaranteeing a good penetration of the drug through the cornea. This treatment may or may not be associated with administration of sulfonamides *per os* and protein therapy according to the gravity of the case.

In ocular diseases caused by various types of streptococcus the sulfonamides are of great value. Conjunctivitis caused by streptococcus and corneal disturbances of the same origin can also be influenced by the sulfonamides applied locally, repeated mention being found in the literature as to the good results obtained by application of the drug.

The action of the sulfonamides is much more efficacious, specifically sulfathiazole, in ocular diseases of staphylococcal origin. It is known that the staphylococcus is the germ that is probably responsible for the greatest number of ocular disturbances of bacterial origin: hordeolum, which is nearly always of staphylococcal origin, and blepharitis, which is frequently caused by the same bacteria, are benefited by the local use of 5-percent sulfathiazole ointment, the action of the other sulfonamides being far less effective and sometimes nil. Thygeson⁴⁷ mentions good results obtained in the treatment of blepharitis with the use of 5-percent sulfathiazole ointment applied 6 times daily at regular intervals in the form of massage of the palpebral border. In recent cases the treatment is always effective, whereas in old chronic cases it is sometimes necessary to associate other therapeutic measures. In the latter cases epilation of the infected cilia and expression of the meibomian glands are sometimes essential. My own clinical experience with a large number of patients thus treated within the last two years has confirmed this observation. Also in cases of staphylococcal impetigo and infected eczema of

the lids sulfathiazole ointment has given excellent results.

Corneal ulcers of staphylococcal origin usually heal better with the use of powdered sulfadiazine (Thygeson⁴⁸) applied to the conjunctival cul-de-sac at intervals of 3 or 4 hours. It is always necessary in these cases to eliminate the coexisting blepharoconjunctivitis in order to avoid recurrences. I have used iontophoresis of solutions of 5-percent sodium sulfacetamide in many cases of corneal ulcers of staphylococcal origin and results have invariably been good. I usually give applications of 3 to 5 minutes' duration with a current of 2 Ma. In cases of conjunctivitis caused by staphylococcus I have also used, and with very good results, instillations of collyria of 15-percent sodium sulfacetamide, repeating the instillations more or less frequently (every hour or at longer intervals) according to the evolution of the case. Robson and Scott⁴⁹ also mention having obtained good results with instillations of this same drug in concentrations of 2.5 to 30 percent in the treatment of conjunctivitis of various origins.

Chronic conjunctivitis constitutes a therapeutic problem that it is sometimes difficult to solve. From the bacteriologic point of view the germ most frequently found is the *Staphylococcus aureus*. Thygeson and Braley⁴⁴ with clinical experimentation found that the use of 5-percent sulfathiazole ointment was effective in the treatment of these cases as against the uselessness of the classical treatment. They also found that in cases wherein the *Morax Axenfeld* diplobacillus was present, treatment with zinc sulfate was useless until the staphylococcal factor was eliminated. Clinically we have found the treatment of chronic conjunctivitis by sulfonamides very effective, good results having been obtained with the application of collyria of 15-percent

sulfacetamide. In cases of chronic conjunctivitis it is very important to eliminate the foci of blepharitis, which are nearly always caused by the staphylococcus. These foci may lack subjective symptoms and objectively only a careful examination will show small scales, which are visible with a magnifying lens, on the roots of the lashes. It is therefore indispensable in cases of chronic conjunctivitis, in addition to applying ointment or collyria of sulfa to the conjunctival cul-de-sac, to apply this ointment also to the palpebral border.

One of the germs that most frequently causes acute catarrhal conjunctivitis is the Koch Weeks bacillus (*Haemophilus influenzae*). Experiments carried out *in vitro* by Guyton,¹⁴ which have been clinically confirmed, show that the sulfonamides (sulfanilamide and sulfapyridine) have a favorable action in the treatment of this conjunctivitis. Thygeson and Braley⁴⁴ found that whereas with the staphylococcus, which is also a frequent cause of acute conjunctivitis, the action of the classical methods of treatment is manifestly inferior to that of sulfathiazole, with the Koch Weeks bacillus and with the pneumococcus the action of the classical medication and of sulfathiazole is more or less equivalent. Practically, we may deduce from this statement, the advantage of the systematic use of sulfonamides which in the worst hypothesis could only have an equivalent action to that of the best medication. My experience confirms that the use of 15-percent sulfacetamide is effective in the treatment of acute catarrhal conjunctivides caused by the Koch Weeks bacillus, by the pneumococcus, or by staphylococcus.

The pneumococcus causes ocular disturbances such as conjunctivitis, corneal ulcerations, dacryocystitis, and the like. Favorable results in the treatment of these conditions with the local use of

powdered sulfapyridine in corneal ulcers has been mentioned (Johnstone¹⁸). Due to the avascular nature of the cornea large concentrations of sulfonamide are necessary in order to obtain an effective bacteriostatic action against the pneumococcus, therefore iontophoresis with sulfathiazole or sulfadiazine is indicated. I have obtained very good results with iontophoresis with sodium sulfacetamide in cases of corneal ulcers due to pneumococcus. As the disease is of a serious character, however, I always associate oral administration of the drug and other therapeutic agents indicated, such as foreign-protein therapy.

Pneumococcic conjunctivitis (catarrhal, acute, or chronic) generally does not endanger the eye and responds equally well to the classical treatment and to sulfonamide treatment.

The pyocyaneus bacillus causes severe corneal ulcerations which lead to perforation and panophthalmitis within a few hours. Ocular manifestations of pyocyaneus infection although responding badly to ordinary treatment can be effectively treated with sulfadiazine iontophoresis (Von Sallmann⁴⁸), by instillation of sulfacetamide collyria (Robson and Scott³⁸), or by combined oral and local administration of sulfadiazine (Thygeson and Stone—ref. by Thygeson⁴³). Sulfapyridine was used by Lepard²² and by Joy¹⁹ before the discovery of the other sulfas. In a serious disease such as ulcers of the cornea due to pyocyaneus⁹ it is necessary to act quickly, therefore associated administration orally and by iontophoresis of the drug is recommended in order to obtain and maintain a concentration of sulfonamide which will check the growth of the germ.

Morax Axenfeld's diplobacillus causes conjunctivitis and corneal ulcerations which respond well to local sulfonamide treatment with 5-percent sulfathiazole

ointment.⁴⁴ I have used 15-percent sodium sulfacetamide with very good results in cases of conjunctivitis caused by this germ, and iontophoresis with a 5-percent sulfacetamide solution is also effective in the treatment of corneal ulcers of this same origin.

Meningococcus rarely causes conjunctivitis. Recently, however, Thygeson⁴⁶ mentioned a case of primary meningococcal conjunctivitis which responded well to treatment with sulfadiazine orally combined with applications of 5-percent sulfathiazole ointment every two hours.

The coli bacilli rarely cause pathologic disturbances in the eyes, but treatment with sulfonamides (sulfathiazole and sulfadiazine) applied locally should be the treatment of choice. Rare, too, are inflammations caused by the bacilli of the *Proteus* group or by the Friedländer bacillus. But either one responds well to local sulfonamide treatment.

Prophylactically, instillation of 15-percent sodium sulfacetamide has been found beneficial during the preoperative and postoperative period, the secretion found in the dressings after surgical operations being manifestly decreased, probably due to lesser irritation caused by this collyrium in comparison with other antiseptic agents.

Guyton and Woods,¹⁵ who obtained good results with the prophylactic use of sulfadiazine orally in cataract extractions, mention having observed undesirable irritations due to the application of powdered sulfadiazine to the conjunctival cul-de-sac.

Igersheimer¹⁷ relates the dramatic results obtained with injections of sulfanilamide into the anterior chamber in a case of purulent endophthalmitis. Bacteriologic examination of the purulent aqueous revealed nothing. With two injections of 0.2 c.c. repeated twice infection ceased. Previously, up to the time of

the injections the patient had been under the action of sulfonamide administered orally.

Puga³⁴ also mentions good results obtained from intravitreal injection of neoprontosil in a case of abscess of the vitreous. He also reports having obtained a cure of an ulcer with hypopyon following chronic dacryocystitis. After irrigation of the lacrimal sac with the same neoprontosil, the dacryocystitis disappeared and cure of the ulcer was effected within a few days.

The treatment of dacryocystitis with lacrimal-duct irrigation with sulfonamide solutions certainly causes an improvement and sometimes even a temporary cure of the infection, the secretion disappearing. Definite results, however, are less noteworthy, for if there is no permeability of the excretory lacrimal pathways; inflammation recurs within a short time. In cases wherein the pathways are permeable, however, irrigation with a solution of sulfacetamide or with other similar solutions effect very good results.

In acne rosacea, the lesions of the skin of the face may extend to the skin of the lids. Of an unknown origin, this disease responds unfavorably to various therapeutics. Generally, the external manifestations of the disease which cause the greatest discomfort to the patient are not really the result of the disease but of the staphylococcal infections that occur. For these cases Wise⁴⁹ recommends the use of 5-percent sulfathiazole or sulfadiazine ointment applied locally several times daily.

Adequate use of the sulfonamides in the treatment of ocular diseases, with attention to proper indication and in the doses which clinical experimentation has found advisable, is a decisive element of unquestionable value in the therapy of a large number of pathologic conditions of the visual apparatus. The possibility of

the effective local use of the sulfonamides in ophthalmology has opened up new fields, and in the future it is possible that the use of these drugs will be even more generalized.

SUMMARY

The fact that the sulfonamides are almost innocuous to the ocular tissues when applied locally, their easy penetration when thus applied, the almost complete absence of symptoms of intolerance to this kind of sulfonamide therapy, and the great effectiveness with which the drug acts in several eye diseases make it probable that the topical use of sulfonamides will largely supplant their oral administration.

Sulfanilamide, sulfathiazole, sulfadiazine, and sulfapyridine, especially the former three, are of generalized use for topical therapy in ophthalmology. The fact that sulfanilamide is soluble in water only up to 0.8 percent and that the other sulfas are still less soluble explains why at first, when only aqueous collyria were tried, local sulfonamide therapy did not make headway. Insufflation of powdered and microcrystal sulfonamides, their local application in properly chosen ointments, the use of sodium derivatives, which are more soluble, the previous use of substances which break the surface tension and thus propitiate a larger penetration of sulfonamides through the cornea, the use of iontophoresis and other methods have been tried subsequently with good results and large concentrations of the drug in the ocular tissues are obtained, higher, indeed, than the concentrations achieved when oral or parenteral administration is used. Moreover, this high concentration is reached in a very short time. The possibility of combining local treatment of immediate effect and general treatment of delayed but constant effect is advantageous. Association of fever ther-

apy increases the penetration ration of the drug. So does local inflammation.

Since sulfonamides have only bacteriostatic action, it is essential that the drug be applied frequently; repeated instillations, application of suitable ointments, and iontophoresis appear to be the choice methods.

Phenomena of general intolerance for the sulfonamides during their topical use have not been mentioned so far. Local intolerance revealed by lid dermatitis and conjunctivitis has been mentioned; it always subsides as soon as the treatment is discontinued.

Therapeutic indication for sulfonamides locally in virus diseases is: in cases of inclusion conjunctivitis and trachoma. In the latter, combined simultaneous massage and iontophoresis of the palpebral conjunctiva with the electrode, thus effecting drug penetration and at the same time destruction of the folliculi mechanically, have given good results.

In gonococcic conjunctivitis good results have been reported from the local use especially of sulfadiazine and sodium sulfacetamide. The seriousness of the disease, however, justifies combined local and oral treatment. In cases of streptococcus, pneumococcus, and Koch Weeks inflammations of the eye, sulfonamides are effective but have not proved themselves better than the other therapeutic agents, except in cases of corneal involvement, where iontophoresis is paramount. But in blepharitis, conjunctivitis, and corneal involvement due to staphylococcus, the topical use of sulfonamides is far superior to any other treatment. Thus in conjunctivitis, in general, the local use of sulfonamides is justified as a routine treatment.

Ocular inflammation due to *B. pyocyaneus* has been treated with success with local applications of sulfonamides, especially with iontophoresis of sulfadiazine.

Inflammations due to *B. coli*, *B. proteus*, and *K. friedlander*i have also responded favorably to local sulfonamide therapy.

Prophylactically, before and after ocular operations, the use of collyria of highly soluble sodium sulfacetamide has been advantageous.

Innocuous injections of sulfonamide solutions into the anterior chamber and

into the vitreous chamber have been reported, apparently with good clinical results.

Local sulfonamide therapy is very effective in a number of well-defined eye diseases, provided proper dosage and adequate means of administration are used.

DACRYOCYSTITIS: THE PART PLAYED BY SYPHILIS IN ITS ETIOLOGY

JOHN O. WETZEL, M.D.

Lansing, Michigan

In the ophthalmologist's daily routine, inflammation of the tear-ducts is a fairly common finding. When a search is made for the underlying cause, it is usual to find that the trouble started, not in the lacrimal sac itself, but rather in the duct—because something had occurred to obstruct the duct. When any of the body's secretions are held back, multiplication of the retained bacteria is the regular result. The inflammatory condition thus induced, may, however, be due to any one of many causes; when it becomes chronic, it is often extremely difficult to control. Under such circumstances we must delve deeper into the etiology, for local measures of relief are of no lasting value if we do not know the precise nature of the infection with which we are dealing.

Relation of lacrimal-tract infections to nasal disease. The lacrimal apparatus, on account of its close relation to the nose, is likely to be involved in any disease condition affecting the upper respiratory tract. Because this fact is clinically established, rhinologists and ophthalmologists (if they are consulted) often assume, in any lacrimal-tract disturbance, that nasal-sinus disease is the underlying factor, and so make no further investigation.

Congenital malformation. Old-school ophthalmologists referred most pathologic conditions of the lacrimal apparatus to congenital malformation. The modern textbooks do not lay so much stress on anomalies of structure, but there is no doubt that malformed organs in any part of the body are more prone to disease than completely normal ones. Schnyder, writing in 1920 (which ranks him with

the moderns), gave examples of hereditary disease of the lacrimal apparatus which he demonstrated were dependent upon anomalies in the conformation of the nasal bones. Such anomalies can be passed on from one generation to another. Schnyder's argument was that the osseous portion of the lacrimal canal—that is, the lacrimal bone itself—the ascending portion of the maxilla, and the lacrimal process of the inferior turbinate—all being parts of the facial skeleton—have definite forms for races, families, and individuals, so may vary exactly as do the shapes of nose or temporal bones. If the lumen of the lacrimal canal is abnormally contracted because of bony malformation, individuals or families presenting this anomaly will be prone to have "watering eyes."

Congenital lymphoid-tissue hypertrophy. Other writers—for example, Meller—incriminate lymphoid tissue rather than bony structures. If an overgrowth of such tissue exists—and this tendency to lymphoid-tissue hypertrophy may well be inherited—any infection or other stimulation might cause swelling which would close off the lacrimal canal and so induce dacryocystitis.

Determination of the active infective agent. But even if we accept these etiologic concepts we are still confronted with the necessity of determining the active causal factor. My attention was particularly drawn to this phase of the subject by two patients who came under my care on account of a dacryocystitis on the left side. The histories are as follows:

CASE 1. Because of a painful swelling of the

left eye and left side of the nose, a housewife, aged 54 years, presented herself for examination. She stated that for three months previously there had been a discharge of pus, with periodic swelling at the inner canthus on the left side. The swelling had been opened and drained several times, but the lesion had remained obstinate to treatment.

Examination showed the vision to be: R.E. 6/7.5; L.E. 6/12 (uncorrected). There was swelling at the left inner canthus, so great as entirely to obliterate the outlines of the lacrimal fossa. The swelling on the left side of the face extended downward as far as the mandible, and there was preauricular and cervical lymphadenitis. Routine laboratory examination reported a positive Kahn test, and, guided by this indication, intensive antiluetic therapy was instituted, with hospitalization. The patient was discharged cured at the end of 10 days, although two months later it was necessary to perform a dacryocystorhinostomy in order to do away with the troublesome epiphora.

CASE 2. A laborer, 41 years old, came complaining of a periodic swelling of the left side of the face, especially at the left inner canthus. In the past he had been able to reduce the swelling by massage, but at the last attack the affected region had been too painful to permit manipulation, which induced him to seek relief.

Examination showed vision in each eye to be 6/30, but with his present correction, 6/7.5. There was a painful indurated mass over the site of the lacrimal fossa, although the anatomic landmarks were obliterated, and the lymph glands much enlarged. Immediate relief was afforded by drainage of the affected area, and when the laboratory reported that serologic study had revealed syphilis, energetic antileuetic therapy was immediately started. Recovery from the eye condition was prompt, and there was no recurrence during the two months we were able to follow up the case.

Syphilis as an etiologic factor. The demonstration of syphilis in both these cases prompted me to attempt to determine what percentage of cases of tear-duct inflammation is due to an underlying luetic infection. I found little on ocular syphilis, while the literature on lues of the lacrimal apparatus was very meager indeed. For example, in the pamphlet on "The diagnosis and treatment of ocular syphilis" issued by the New York Tuberculosis and Health Association in 1943, one finds:

Lacrimal apparatus: A primary syphilitic lesion of the lacrimal gland rarely occurs. Inflammation of the lacrimal gland (dacryoadenitis) appearing in the tertiary stage of syphilis, is characterized by a painless or slightly tender, localized tumor in the region of the gland. Primary and secondary lesions of the tear-passages seldom occur. Syphilitic lesions of the lacrimal sac and nasolacrimal duct may occur in the tertiary stage of syphilis. They are frequently secondary to syphilitic lesions of the adjacent parts, as, for example, syphilitic inflammation of the medial and lower angle of the orbital margin.

HISTORICAL REFERENCES

The oldest work on syphilis of the eye to which I have access—Thomas Hewson's "Observations on the history and treatment of the ophthalmia accompanying secondary forms of lues venerea," published in London in 1824—has nothing whatever to say about luetic infection of the tear ducts, although it makes most interesting reading on the general subject of ocular syphilis. Neither is dacryocystitis mentioned as etiologically dependent on syphilis in any of the standard works on ophthalmology in use during the remainder of the nineteenth century. Indeed, the present century was well advanced before such a possibility was recognized by either general practitioners or ophthalmologists in eye work or syphilology.

The 1934 edition of Stokes' "Modern clinical syphilology" discusses Mikulicz's syndrome, which is defined as "a chronic symmetrical painless enlargement of the salivary or lacrimal glands." We are told that its "etiology is probably a chronic infection, tuberculosis and syphilis having been demonstrated in some cases." A canvass of the literature shows that primary syphilis was occasionally demonstrable in the lacrimal gland, the dacryocystitis being secondary to it. Such a case was reported by Anargynos in 1901. Tuberculosis of the inner canthus was the first diagnosis. Simultaneously with the swelling of the gland, hypertrophy of

the conjunctiva occurred, there was a scattering of small yellowish nodules which later coalesced, and an accompanying adenitis in the preauricular lymph-glands. The lacrimal gland was removed, but pathologic study showed no tuberculosis. Four weeks thereafter the patient's body displayed a papulomacular exanthema, with generalized lymph-gland involvement. All the manifestations promptly subsided under antiluetic treatment, which in 1901 was considered proof positive of syphilitic infection.

The 36-year-old woman seen by Luedde in 1911, gave a history of "an abscess of the corner of the left eye" of 4 or 5 weeks' duration." Examination showed what appeared to be "an ordinary inflammation of the lacrimal sac, except that the bulk of the swelling was higher than usual." But the therapy usually efficacious in dacryocystitis had no effect. Three weeks elapsed and the patient "even seemed to be getting worse." An inquiry into the woman's social antecedents offered a syphilitic infection as a possible explanation. Acting upon this hint, Luedde pushed antiluetic measures, with immediate subsidence of all the ocular manifestations. The author remarks, "It is evident that we were dealing here with a gummatous process springing from a latent lues of long-standing. The location of the trouble, together with the subjective symptoms (overflow of tears, excessive secretion, swelling, and others), and the rarity of luetic processes of this type obscured the diagnosis."

Is the left eye more commonly effected?
Inasmuch as both my own patients suffered from infection of the *left* lacrimal duct, it has been of especial interest to me to note that all the preceding cases were of leftsided dacryocystitis. I can see no reason why the left side should be more often involved and the fact is probably

only coincidental, but it will be of interest to note, as such cases are more often reported, whether or not the condition has a predilection for the left side.

In the case of Parker, reported in 1913, the patient was a boy, aged 6½ years, with a history of having suffered since six months of age with bilateral purulent dacryocystitis. The author tells us,

... We believed the case to be one of congenital obstruction of the ducts. These cases usually depend upon failure of complete absorption of the epithelial cord, which ... in the embryonic state is developed from an ingrowth from the epithelial surface. Such cases are usually unilateral and are characterized by overflow of tears and acute attacks of dacryocystitis beginning shortly after birth. They are generally completely cured by the passing of probes, rupturing the occluding membranes. This child was treated in this manner, but after prolonged probing, the treatment continuing many weeks, and failures to secure drainage, both lacrymal sacs were removed, with a complete cure of the dacryocystitis.

Syphilis was not, however, suspected until four years later, when the boy returned to the hospital with a severe interstitial keratitis. At the time of this second entrance, the routine examination included a Wassermann test, which gave a strongly positive reaction. Profiting by this experience, Parker had a Wassermann done on another child who just then came in with an acute dacryocystitis, and secured an equally positive reaction. He remarks that he had learned the lesson that "in all cases of bilateral epiphora or dacryocystitis coming on without definite history" a Wassermann test should be made.

The discovery of the Wassermann test facilitated the detection of a luetic origin in all sorts of eye affections, just as it did in almost every other field of medicine. In 1914, Igersheimer published a series of cases wherein hereditary syphilis had affected the lacrimal apparatus. He pointed out that many instances of dacryocystitis wherein the cause had been attributed to

nasal infection, were in reality cases of hereditary syphilis of the upper respiratory tract, either in the submucosa or the underlying bony structures, which had produced stenosis of the lacrimal passages, with resulting dacryocystitis. The fact that many children so affected also have chorioretinitis, or parenchymatous keratitis—both of which are known to be frequently syphilitic in origin—is a strong confirmation of this theory.

Igersheimer gives a more detailed consideration to the luetic origin of many instances of lacrimal-duct inflammation than any who went before him. He divides the cases into three groups:

(1) Those in which the origin cannot be demonstrated, but the present appearances made it reasonable to assume that earlier in life stenosis of the nasal passages had occurred, resulting in lacrimal-duct inflammation.

(2) Those wherein syphilitic changes in the nose could not be demonstrated, but there was a history of syphilitic infection.

(3) Those wherein a "saddle-nose" or other nasal deformity associated with syphilis existed as positive proof of the etiology of the lacrimal-tract involvement.

In 1915, Potter told the members of the Laryngological Section of the Royal Society of Medicine of London of the case of a girl aged 12, concerning whom no history of her previous condition was obtainable, "since the child was sent to me from a work house infirmary." On examination of the child after she reached the hospital, widespread destruction of the septum and left side of the nose was discovered, while the uvula was entirely absent. We cannot, today, share the surprise of both speaker and audience that a bilateral dacryocystitis should have resulted under such circumstances.

The thesis that Guilini presented at Munich in 1914 concerned luetic infection

of the lacrimal gland, and in the same year—that in which the first World War began—Dewabripont published a monograph with the imposing title "Contribution to the study of the bacteriological and histological relationships between disease conditions of the nose and of the lacrimal ducts," containing an elaborate classification of the causes of dacryocystitis, the seventh of which was "Syphilis," which, he stated, was regularly secondary to syphilis of the nasal bones. Dewabripont was a Belgian, and probably familiar with Kalt's article in the volume of the "Encyclopédie française d'Ophthalmologie," which was published in 1909. Kalt states that as far back as the days of Boerhave, syphilis of the nose was recognized as being likely to cause blockage of the lacrimal ducts, and subsequent inflammation, and continues by listing four "observations" culled from French literature, namely those of Alexander, Thiry, Galezowski, and Panas.

... Alexander's patient showed osteo-periostitis, necrosis of the maxillary bone, and a fungoid condition of the lacrimal sac; Thiry's had periostitis of the left temporo-mandibular articulation with a syphiloma in the region of the lacrimal sac, all having appeared eight months after the original luetic infection. In Galezowski's case the syphiloma appeared as a secondary manifestation, terminating as gummatous hyperplasia of the anterior wall of the sac. Panas saw a man, aged 45 years, who was infected with syphilis at age 25, but was otherwise in good health. He now presented a huge fungating mass in the region of the lacrimal sac of the left side, which at first sight suggested a cancer. But as he also had characteristic lesions of the tonsils and nasal bones, the true nature of the "growth" was recognized, and everything cleared up promptly when anti-luetic measures were instituted.

The author remarks that the only dangers in diagnosing these cases lie in confusion with tuberculosis. And 20 years later we find Kemler making a similar statement, only warning us not to confuse syphilis with foci due to other infections than that of the spirochete.

In 1921 Pais reported a case of "syphilitic dacryocystitis," and from that time forward there was increasing recognition of the importance of this protean disease in lacrimal-tract infection. Reports were published by Treacher Collins (1922) in England; Cowper (1922) and Derby and Cheney (1924) in this country; and in France by Rollet and Colrat (1925), Hudelo d'Allaines and Rabut (1926), and Morel and Gest (1929). The case of Vogt, quoted by several authors, turns out upon translation of the original publication to have been attributed not to syphilis but to gonorrhea. However, Fahmy, an Egyptian, writing *in extenso* on the etiology of dacryocystitis, makes but a brief mention of the spirochete as having appeared in any of his microscopic investigations. And Desvignes, as recently as 1938, remarked that he believed it his duty to publish his clinical history of a 36-year-old woman "because of the rarity of these cases and the importance of establishing an exact diagnosis in order to institute an etiologically rational treatment."

The most recent paper to come to my attention, in which mention is made of the etiologic importance of syphilis in dacryocystitis, is that of Garfin published in January, 1942. In sharp contrast to earlier writers, he states that "syphilis not infrequently occurs as a primary disease of the lacrimal sac, or of the skin overlying it. It may also extend from the inner canthus to involve the sac." He adds, "Through obstruction of the lacrimal canal, syphilis may lead to non-syphilitic dacryocystitis," and he concludes by mentioning that among his first 25 operations on lacrimal sacs he found two external fistulae due to acquired syphilis.

An examination of textbooks, recently published or revised, provides no more information on which exact percentages might be based. Tassman in his "Eye

manifestations of internal diseases" (1942) says, "Dacryocystitis . . . may result from cicatricial contraction following ulcerations occurring in syphilis and tuberculosis." The fourth edition of Neame's "Handbook of ophthalmology" (1942, p. 78) merely states, "Inflammation of the lining mucous membrane of the naso-lacrimal ducts is catarrhal, tuberculous or syphilitic . . . occasionally syphilitic periosteitis . . . for tumors of the upper jaw may cause obstruction by external pressure on the nasal duct," resulting in dacryocystitis.

SUMMARY

1. Inflammation of the tear ducts is frequently referred to accessory-nasal-sinus disease, and the possibility of other etiologic factors overlooked.

2. Nineteenth-century ophthalmologists considered congenital anomaly of the facial bones or of the lymphoid tissue of the lacrimal region capable of furnishing an environment favorable to dacryocystitis.

3. When treated by antiluetic measures, two cases of acute dacryocystitis seen by the author promptly subsided. This led him to attempt to determine the percentage of cases of tear-duct inflammation that could be traced to syphilis.

4. A review of literature disclosed but a few recorded instances of proved syphilitic dacryocystitis, and, as late as 1938, the "extreme rarity" of the condition is emphasized.

CONCLUSIONS

In comparatively few cases of dacryocystitis has syphilis been recognized as the etiologic factor. It is probable that more careful laboratory examinations might reveal many unsuspected cases.

Therefore, it would seem desirable that serum tests become a regular part of the examination in all cases where the causal factor is in doubt.

NOTES, CASES, INSTRUMENTS

THE USE OF SCLERAL RESECTION IN HIGH MYOPIA*

REPORT OF A CASE

W. E. BORLEY, COMDR. (M.C.) U.S.N.R.

AND

O. R. TANNER, M.D.

San Francisco, California

Loss of vision in cases of high myopia associated with progressive degenerative changes in the retina and choroid is not uncommon. It is usually so slowly progressive that the patient is not aware of any sudden decrease in the vision; and occasional changes in the patient's glasses are sufficient to relieve the individual. On rare occasions, however, the ophthalmologist is faced with the problem of treating a malignant myopia, with degenerative changes, in which the patient is keenly aware of the rapid failure of vision, and changes of the lenses are of no benefit. Such loss of vision may occur over a period of weeks or several months and may incapacitate the patient to the extent that he is desperately in need of help.

Scleral resection in such desperate cases was suggested to one of us (W. E. B.) in 1934 by Lindner; but he stated that he had never attempted such a procedure in the absence of retinal detachment.

A review of the literature reveals only sporadic accounts of operations performed in these cases of high myopia in which other complications indicating surgery were not present. Müller,¹ Elschnig,² Lindner,³ Pischel,⁴ Borley,⁵ and others, however, have had rather gratifying re-

sults with scleral resection in more or less hopeless cases of retinal detachment in which previous operations had failed and in which myopia was the underlying disease. Arlt, Wolfe, Perinaud, and Galezowski are reported by Hildesheimer⁶ to have attempted shortening the eyeball by excision of a band or bands of sclera to relieve high myopia and to improve retinal detachments in myopic eyes. Results were apparently very unsatisfactory, and there were many serious complications which made these procedures useless.

In 1903, Müller¹ described his operation of scleral resection for retinal detachment in high myopia, and Lindner later modified this procedure. In 1911 Holth⁷ presented an operation for reducing myopia by trephining the sclera in the preëquatorial region. He reported results of his operation in seven cases of retinal detachment and in two cases of high myopia in which no detachment existed. He claimed a shortening of the anterior-posterior axis of the globe was produced and a reduction in the degree of the myopia; but he gave no report of visual improvement.

In 1926, Müller⁸ presented another operation for decreasing myopia by severing the superior oblique muscle. He reported 25 cases, 21 of which were in highly myopic patients. The results in these cases were said to be a negligible motor loss, enophthalmos of about 3 mm., decrease in the degree of myopia by 3 to 6D., retrogression of the retinal and choroidal changes, and improvement of visual acuity.

In 1937 Hildesheimer⁶ reported the use of the electric cautery, in the form of a loop, to excise sclera for the reduction of myopia. He recorded two such cases, in each of which there was a unilateral high

* From the Department of Surgery, Division of Ophthalmology, Stanford University School of Medicine.

myopia, one complicated by exophthalmos, and the other, by a grayish prominence of the peripheral retina which he called an imminent detachment. Both eyes so operated upon were reported to be improved.

Spaeth,⁹ in the latest edition of his textbook on ophthalmic surgery, devotes a page to "Scleral surgery for high myopia," and considers Lindner's recommendations for scleral resection. However, he gives no report of any use of the operation in the absence of retinal detachment.

Thus the problem of treating a severe and progressive myopia with degenerative changes and rapid failure of vision has been only occasionally reported as successful. It was therefore thought that the following report of a case with the technique used and the visual improvement noted might add to our present knowledge of high-grade myopia and the possibilities of a method of successful surgical treatment.

CASE REPORT

Miss P. E., a white nurse, aged 56 years, entered Stanford Eye Clinic on November 5, 1940, for examination because of a recent disabling loss of vision of several weeks' duration. Vision of both eyes had always been subnormal due to a high degree of myopia, but she had been able to carry on with her nursing with

changes in her glasses until several weeks before seeking medical advice. She had worn glasses for nearsightedness since the age of five years. At the time of entry she stated that there had been some loss of vision in the left eye for the previous year, but there had been a more rapid blurring and loss of vision in both eyes during the several weeks previous to entry. She had only recently become unable to read a newspaper, whereas shortly before she had had no difficulty.

At examination the following observations were made: Corrected vision was, right eye, 15/200; left eye, the ability to detect hand movements at 2 feet. Glasses worn were—right eye, $-17.75D.$ sph. $\approx -1.00D.$ cyl. ax. 80° ; left eye, $-18.75D.$ sph. No change in lenses improved the vision. The eyeballs were protuberant in appearance. Ophthalmoscopically, there were many vitreous opacities in each eye, and the fundi showed irregular pigment accumulations at the posterior poles and large extensive areas of choroidal atrophy with a definite ectatic appearance in that region. The changes were more marked in the left eye. A very restricted eccentric field of vision in the left eye was present to objects of 30 mm. diameter. The visual field of the right eye showed extensive loss, but with retention of some of the central portion of the field (fig. 1).

Considering the seriousness of the find-

FIG. 1 (Borley and Tanner). Visual fields before operation, January 9, 1941. Test object, 30 mm., white. Field only slightly larger to hand movements.

FIG. 2 (Borley and Tanner). Visual fields three years after operation, September 5, 1944. Test object, 30 mm., white.

ings and the apparent recent rapid loss of visual acuity, it was thought advisable to perform some operation that might prevent further progress of the disease. It was believed that a scleral resection might offer some hope, and operation on the left eye was performed on January 22, 1941. The resection of the sclera was done on the temporal side, 11 mm. posterior to the limbus, from the 12- to the 6-o'clock positions. A strip of sclera 2 mm. wide was removed. The technique was similar to that described in a previous paper by one of us (W. E. B.),⁵ with the exception that, in removing the strip of sclera and bringing the sutured edges together, repeated paracenteses were required to allow escape of fluid, with consequent lowering of the intraocular pressure, in order to replace the protruding choroid. It was not considered advisable to puncture the vitreous body to relieve the tension because of the possibility of injuring the retina and causing a retinal detachment.

The postoperative course was uneventful. The field of vision and the visual acuity did not immediately change, but this eye remained essentially the same. Within the next two months there was a progressive loss of vision in the right eye, and it seemed likely that all useful vision might be lost. Scleral resection was proposed for the right eye, and the patient gave her permission. Vision just before operation in this eye was 15/200, with difficulty. There was further limitation of the field of vision.

Scleral resection was done on the right eye on June 18, 1941. A 2-mm. strip was resected as on the other eye, from the 12- to the 6-o'clock positions on the temporal side. The choroid was cauterized with 3-percent sodium hydroxide and the scleral edges approximated with no. 0000 chromic catgut after aqueous had been repeatedly released by means of paracenteses.

The postoperative course was similarly uneventful. The vitreous after several months appeared clearer, and the fundus was more easily seen. The patient stated that her vision had improved and that she could get about definitely better. There seemed to be slight but definite improvement from that time on, and by January, 1943, the condition seemed to have reached a stationary point, with demonstrable improvement in visual acuity and visual fields, particularly in the right eye.

At the time of the last examination on September 5, 1944, the corrected vision was: R.E. 15/70; L.E. ability to count fingers at 2 feet. The glasses worn at the time of entry to the clinic in 1940 could not be improved upon. With a hand magnifying glass, the patient could read Jaeger 8 type print with difficulty with the right eye, and had managed to read part of a newspaper daily for the past year. Visual fields were essentially the same as in January, 1943 (fig. 2). There were no further changes in the fundi, except that in the right eye an area of choroidal scars and pigmentation similar to that seen after operations for retinal detachment could be seen far temporally in the area of the scleral resection.

DISCUSSION

The case just described demonstrates that scleral resections may be successfully used in the absence of retinal detachment. The main point of difficulty arises when the protruding choroid is replaced and the sutures tied. Great care must be used to avoid injury to the choroid with consequent hemorrhage. The simple expedient of anterior-chamber paracenteses repeated at about five-minute intervals during the suturing greatly facilitates the closing of the wound. Cauterization of the choroid with sodium hydroxide is done as in all types of scleral resection. It

is our opinion that cases of this type derive some benefit from this operative procedure, either in improvement or in prevention of further progress of the disease to ultimate total loss of vision from degenerative changes or retinal detachment.

CONCLUSIONS

Scleral resection in highly myopic eyes

with degenerative changes but without retinal detachment is feasible and possible, without injury to the retina or choroid. With the use of this procedure the progress to blindness from degenerative changes or retinal detachment in these eyes may be delayed or prevented.

PENICILLIN ADMINISTERED LOCALLY IN GONORRHEAL OPHTHALMIA

SENSITIZATION REACTION

ELMER A. VORISEK, MAJOR (MC),
A.U.S., AND ALBERT L. EVANS,
CAPT. (MC), A.U.S.
Atlanta, Georgia

Enthusiastic reports upon the results of penicillin therapy in cases of surgical infection are continuously coming to our attention. Only a limited number, however, record the local use of an aqueous solution of penicillin in the conjunctival sac; nevertheless, they^{1,2,3} speak of gratifying results.

Since penicillin has established an important place in the treatment of gonor-

rheal urethritis, it was anticipated that its intramuscular use in gonorrheal conjunctivitis would result in a satisfactory recovery. However, we were anxious to observe the effects of the local application of the drug into the conjunctival sac in a case of gonorrheal ophthalmia. One particular patient was well suited for this method of local treatment because the infection certainly was a fulminating one, although the cornea was intact and showed no immediate danger of sloughing.

In addition to the excellent result which was obtained from the use of this new drug, this case is reported because of the local drug sensitivity which resulted after prolonged use of the solution, and because of the allergic activation of the lids fol-

lowing later intramuscular injections.

The patient, a white man, aged 40 years, was admitted to the Lawson General Hospital on November 2, 1943. He stated that approximately 12 days before admission the right eye had become injected and had gradually become severely inflamed. Ophthalmologic examination revealed vision: R. 20/100, L. 20/15. The lids of the right eye were moderately red, thickened, very firm to the touch, swollen shut, and were so leathery that they were opened with difficulty, and a lid retractor had to be used. Thick, dirty, yellow pus literally flowed from between the lids, so that the cheek required almost constant wiping. The conjunctival sac was filled with thick pus. The palpebral conjunctiva had the appearance of "raw beefsteak." The bulbar conjunctiva was injected and so thick that a ring of depression was produced around the limbus. The cornea was moderately hazy. The pupil was very small and reacted sluggishly to light. A smear made from the secretions was filled with pus cells and gram-negative, intracellular diplococci, morphologically resembling gonococci. The culture was confirmatory. The left eye appeared entirely normal with a minimal amount of conjunctival injection, and during the entire course of the disease remained uninvolved.

The patient admitted having had a recent attack of gonorrheal urethritis which apparently had subsided following sulfonamide therapy. However, a smear made from a mucoid urethral discharge was positive for the gonococcus.

Atropine sulfate, a 1-percent ointment, was instilled once, and four drops of a saline solution of penicillin (500 units per cubic centimeter) were instilled into the right conjunctival sac every hour, beginning at 5:00 p.m. on the same day. At the end of 16 hours, there was marked objective improvement. The vision, even

under atropine, had improved to 20/40, the purulent discharge had ceased, the lids were less thick, and the conjunctiva was less elevated. Although upon admission the smear from the conjunctival secretions presented many gonococci, a similar examination made on this second day of treatment revealed a complete absence of the gonococci. Beginning at 10:00 p.m. on the second day of hospitalization the penicillin was instilled every three hours, and on the third day, beginning at 6:00 p.m. the strength of the penicillin solution was reduced to 250 units per cubic centimeter. One drop of a 1-percent atropine sulfate solution was instilled each morning during the first week of hospitalization, following which it was administered every third day. Three days after admission iced normal saline compresses were applied to the right eye four times daily.

Daily smears and cultures as well as occasional conjunctival scrapings remained negative until the seventh day when gram-negative intracellular diplococci were again seen. As a consequence of this finding, the penicillin solution (250 units per cubic centimeter) was again instilled every hour for 12 hours, and, subsequently, was again administered every three hours.

The lids became almost normal; there was only mild ptosis, and, although the bulbar conjunctiva was much less injected, the palpebral conjunctiva was only slightly improved.

On the twelfth hospital day, while the penicillin was still being administered every three hours, the lids of the right eye suddenly became very thick, dull red, and leathery, and the epithelium of the skin surface became slightly fissured. In addition, there was almost complete ptosis of the upper lid. The bulbar and the palpebral conjunctiva remained unchanged. Examinations of smears made from conjunctival scrapings were negative. The

clinical appearance was that of a typical drug sensitivity, and, in view of the fact that the atropine solution was being instilled only twice weekly, it seemed evident that the penicillin solution must be held responsible for this reaction. This solution was discontinued immediately, but the atropine and the iced saline compresses were continued.

Rapid improvement occurred by the fifteenth hospital day. The vision in the right eye, under atropine, was now 20/25. The epithelium of the lids began to desquamate, and bland sterile oil was applied externally. On the seventeenth hospital day the external appearance of the lids was normal, and all local treatment was discontinued. The bulbar conjunctiva had a normal appearance, and the cornea was clear. However, there remained considerable palpebral conjunctival injection of the lower lid, with marked thickening and redness of the inferior fornix. The upper lid was almost normal in appearance. Repeated smears and a culture of the conjunctival scrapings were negative, and zinc sulphate solution (0.25 percent) was instilled, one drop four times daily. One week later the strength of the solution was increased to 0.5 percent. The conjunctiva of the inferior fornix gradually became less injected, and all local treatment was discontinued.

Although no urethral discharge was perceptible, several cultures of the urine were reported positive for gonococci. Consequently, on the 36th hospital day 50,000 units of penicillin were injected intramuscularly as follows: 10,000 units every three hours for five doses. Following the final injection at 8:00 p.m., the lids of the right eye became moderately edematous, with partial ptosis of the upper lid; and the conjunctiva became moderately injected. There was no secretion nor discharge and the smears and cultures of conjunctival scrapings remained nega-

tive. This reaction resembled a typical allergic manifestation, which completely subsided in a few days, following the use of iced saline compresses and one drop of a 1 to 1,000 solution of adrenalin hydrochloride four times daily.

After this episode the conjunctival scrapings and urinary cultures remained persistently negative, and the visual acuity was: R. 20/20, L. 20/15. Both the palpebral and bulbar conjunctiva appeared normal and the patient was discharged from the hospital and returned to duty.

Comment. We were encouraged to use penicillin locally in the conjunctival sac after reading the report of M. E. and H. W. Florey³ upon their success with one patient who had gonorrheal ophthalmia neonatorum.

From our experience in this case it would seem that hourly local instillations of saline penicillin should be continued for a period of 12 hours, followed by instillations at 3-hour intervals. The penicillin should be continued until three successive daily smears and cultures of conjunctival scrapings have been reported as negative. Subsequent use of this drug would depend upon the presence of the gonococcus in future smears or cultures of conjunctival scrapings.

The procedure we followed was prompted by our desire to test the efficacy of penicillin locally and therefore we delayed giving the intramuscular injections. We believe it is safe to say that in a patient with gonorrheal ophthalmia, in the absence of an associated genital infection, one would be entirely justified in applying penicillin in saline solution directly into the conjunctival sac. However, should an ophthalmic and a genital Neisserian infection occur concomitantly, both intramuscular and local therapy would be indicated.

Our patient responded so rapidly to local penicillin treatment, that, except

for the usual hygienic measures, no special attempt was made to protect the other eye. It must be remembered that the solutions of penicillin which we used, namely 500 and 250 units per cubic centimeter, were relatively very weak, and using only four drops, reduced each dose roughly to 125 and 60 units, respectively.

CONCLUSION

1. An exceedingly severe case of gonorrheal ophthalmia responded to local treatment with penicillin, yielding negative smears and cultures, in less than 24

hours of treatment.

2. Prolonged use of penicillin locally resulted in a typical drug-sensitization reaction, such as occurs in individuals sensitive to atropine or the mercurials.

3. Twenty-three days after local use of the penicillin was discontinued, intramuscular injection of the drug was given for the gonorrheal urethritis. This procedure was immediately followed by a typical drug reaction in the lids of the involved eye.

Eye Section, Lawson General Hospital.

VOLUNTARY PUPILLARY MOVEMENTS*

J. ROSENBAUM, M.D.
Montreal

This case is of interest in that the patient was able to contract or dilate the pupils at will, without imagining fear, excitement, or horror during the demonstration. She stated that she first noted that she could control the movements of the pupils while looking into a looking-glass when she was about 10 years of age. In the cases recorded in the literature, the pupils dilated when the subject imagined something horrible or that great danger was imminent.

In 1931, Petrovie and Tschemolossow¹ described the case of an oculist, aged 62 years, who had for years been able to

dilate his pupils voluntarily by imagining something horrible. His health had always been good, but in the last few years he had developed some neurasthenic symptoms. The authors observed and described one such experiment lasting 30 seconds, in which the patient gradually dilated his pupils from a width of 3 mm. to 4.5 mm., with simultaneous increased frequency of the pulse rate from 60 to 72 per minute.

It seems that this phenomenon can be explained on the grounds of the existence of a connection between the cerebral cortex and the pupillary center of the oculomotor nucleus, whereby one can control by the will the movements of the pupil through the action of the sympathetic and parasympathetic fibers in the iris muscles. A similar phenomenon is seen in rare individuals who are able to dislocate the shoulder and hip joints voluntarily by

* Presented before the Montreal Ophthalmological Society, October, 1943.

merely relaxing the muscles and ligaments surrounding the articulation.

Chauveau² (1861), Claude Bernard³ (1892), and others have shown that stimulation of any sensory nerve results in a dilatation of the pupils. The dilatation does not depend directly on the physical intensity of the stimulus but is a function also of the state of receptivity of the higher centers, for after ablation of the cerebral cortex the reflex is completely lacking. Strong psychical stimuli act in a manner similar to sensory stimuli and under the excitement of extreme interest, emotion, or fear, pupillo-dilatation is very evident (J. Müller,⁴ 1840). The pupil thus forms, as described by Duke-Elder,⁵ a delicate psychical aesthesiometer; for every stimulation, be it sensory or psychic, which reaches consciousness tends to bring about a dilatation. For this reason pupillary dilatation occurs during the period of excitement in the induction stage of anesthesia, the pupil is contracted in sleep or in narcosis when such impulses are lacking, and on waking from sleep or anesthesia the pupils dilate to their normal size. Pupillo-dilatation occurs on stimulating almost any region of the cortex, whereas a pupillary constriction results if the corresponding half of the cortex is ablated (Trendelenberg and Bumke, 1911). The influence of the cortex, therefore, may become effective either through a stimulation of the sympathetic dilatory mechanism or an inhibition of the autonomic constrictor mechanism.

Case report. An unmarried woman, aged 35 years, an Austrian, came to the writer complaining of having found it difficult to read for the past few months. With the right eye vision was 20/30; with the left eye, 20/20. Under mydriasis there were four diopters of hypermetropia. She had orthophoria, as indicated by the objective cover test and the Maddox rod test.

Ocular movements were normal in all directions. The near point of convergence was 6 cm. She could overcome a prism 14^a base out. Her fundi and fields of vision were normal. Her pupils were, equal, regular, and active, and measured 3 to 4 mm. Her irises were light gray in color. She remembered no illnesses; her general condition was excellent. Her parents were well and healthy.

The patient was seated in a comfortable chair in ordinary daylight illumination; her pupils measured 4 mm. She was asked to dilate her pupils—calmly she looked into the distance and one could see the pupils dilate slowly to about 6 mm.; they remained dilated for about 20 seconds, then she blinked her eyes, and the pupils were seen to return to normal size. She was now asked to contract the pupils—she blinked, looked straight forward, and the pupils contracted to about 2 mm., the contraction lasting for about 20 seconds, after which she blinked and the pupils dilated to 4 mm.

My explanation of the phenomenon is that through training, she had developed control of the cortex, dilating the pupils by inhibiting the pupillo constricting center; conversely, by inhibiting the pupillo dilating center, the pupils would contract.

Another explanation that could be offered is based on the "accommodative process"; namely, when she accommodated for distance, the pupils contracted, and upon relaxing the accommodation the pupils dilated.

Summary. A case of a young woman is presented, who, when she looked straight forward was able to dilate and contract her pupils. It is assumed that this reflex speaks for a connection between the cerebral cortex and the pupillary center of the oculomotor nucleus.

MOTILITY CLINIC*

INTERMITTENT (FACULTATIVE) DIVER-
GENT STRABISMUS. ITS INFLUENCE
ON VISUAL ACUITY AND THE
BINOCULAR VISUAL ACT

HERMANN M. BURIAN, M.D.
Hanover, New Hampshire

R. F. P., a white boy, aged 19 years, reported for examination because his eyes were "turning out." His mother had had a similar condition ever since she was a small girl; otherwise there was no history of strabismus in the family. The patient stated that the turning of his eyes had not been noticed until three or four years ago. At that time he was given glasses. He is able to keep his eyes straight, but when he does so "*everything blurs.*"

Examination. Both eyes were white and quiet; the media were clear; the fundi presented no pathologic changes.

The eyes appeared in a markedly divergent position when the patient fixated a distant object. He used the right eye for fixation, but was capable of changing fixation from one eye to the other at will and on request. He was also able to overcome the divergence of the visual lines by a convergence impulse, but even when he thought that he was keeping his eyes straight there still seemed to be a large angle of divergent strabismus. In the cover test, the angle of squint for dis-

tance measured 12 arc degrees, with a varying amount of right hypertropia. The discrepancy between this relatively small angle of squint and the appearance of the eyes, which indicated a much larger amount of divergent strabismus, was explained by measuring the angle gamma on the perimeter; this angle proved to be -12 arc degrees in the right and -8 arc degrees in the left eye. For near, the angle of squint measured 25 arc degrees, again with varying right hypertropia. When a red filter was placed in front of the right eye in the double-image test, the patient reported 12 arc degrees of crossed diplopia with 12 arc degrees of right hypertropia. When the red glass was placed in front of the left eye the localization of the second image was quite uncertain, but an uncrossed diplopia of 4 arc degrees with 1 to 2 arc degrees of left hypertropia was reported. The horizontal and vertical afterimages of a straight glowing filament, imaged in the right and left eye, respectively (afterimage test), were seen alternately in the dark; in the lighted room (negative afterimages), they formed a cross (normal retinal correspondence). On the synoptophore the objective and subjective angles were 24 B.I. with 7 R.H.; there was only momentary fusion, which could not be held. The rotations presented a definite deficiency of the adduction in both eyes, particularly in the left; otherwise they were normal. The convergence movements were jerky, but the near point of convergence was very good (6 to 8 cm.), and convergence was held well.

* From the Clinical Division of the Dartmouth Eye Institute, Dartmouth Medical School. The case described was demonstrated at a staff meeting of the Dartmouth Eye Institute.

Refraction and visual acuity. R.E. $-0.50\text{D. sph.} \approx -0.50\text{D. cyl. ax. } 90^\circ = 20/20$; L.E. $-0.25\text{D. sph.} \approx -0.25\text{D. cyl. ax. } 90^\circ = 20/20$. The patient continued to have a visual acuity of 20/20 in either eye, as long as he let the other eye turn out. As soon as he straightened his eyes by a convergence impulse, the binocular visual acuity sank to barely 20/200. If lenses of -2.00D. sph. were now placed in front of the eyes the binocular visual acuity increased immediately to 20/20.

Therapy. An advancement with resection of the left internal rectus muscle was performed. Six weeks after the operation there was a residue of divergent strabismus of 6 to 7 arc degrees. The double-image test showed 3 arc degrees of crossed diplopia with 3 arc degrees of dissociated vertical divergence; the corrected visual acuity was 20/20 monocularly in each eye and 20/30 binocularly. The patient was advised to return for recheck and further surgery (advancement with resection of right internal rectus), but could not do so since he entered the service.

COMMENT

Cases such as the one reported are usually diagnosed as intermittent or periodical divergent strabismus. They differ, however, somewhat from the ordinary untreated type of intermittent convergent or divergent strabismus in that the patients are able to keep their eyes straight by a voluntary act of convergence. I prefer, therefore, to classify these cases under the heading of *facultative divergent strabismus*.

The near-point of convergence is always excellent in these patients, although the adduction may be quite deficient in each eye.* They are able to overcome the

strabismus by a convergence impulse, but not all of them have learned to dissociate convergence from accommodation. These patients—such as the one under discussion—then complain that their vision becomes blurred when they keep their eyes straight. It is easily shown by placing minus lenses in front of the patients' eyes that this blurring is due to an accommodative effort accompanying the convergence effort.

There are some other interesting features presented by the patient. He has a dissociated vertical divergence which is very frequent in patients with alternating divergent strabismus. Furthermore, he shows both normal and anomalous retinal correspondence in the double-image test, depending on whether he fixates with the right or left eye. When the red glass is placed in front of the right eye—that is, when the patient sees the white fixation light with the left eye—he reports a crossed diplopia of 12 arc degrees, which is in agreement with the objective angle of squint. But when the red glass is in front of the left eye and the patient uses his right eye to fixate the white light on the tangent screen, the localization of the red image becomes uncertain and the patient reports an uncrossed diplopia of 4 arc degrees (anomalous correspondence).

Such a change in the sensorial retinal relationship with change in fixation is found not only in cases of facultative divergent strabismus. It may be explained in the following way: Anomalous retinal

movement, adduction the result of a conjugate movement (dextroversion or levoversion). These two types of movement are controlled by different centers and may be independently affected. Thus, we see frequently an excess of adduction in convergent strabismus combined with insufficient convergence; or we may have a divergent strabismus with deficient adduction but normal convergence. The choice of operation for strabismus should be based on the behavior of the rotations which can alone be influenced directly by surgery.

* Convergence and adduction should be strictly separated. Convergence is a disjunctive

correspondence is a condition that is acquired on the basis of usage. When the patient fixates with the habitually fixating eye (in this case with the right eye), he uses his eyes in a way that is normal for him and he localizes the second image according to the acquired anomalous retinal relationship. But when he is suddenly forced to fixate with the habitually deviating eye (in this case the left eye), he is faced with unusual conditions. He then reverts to the more or less dormant innate normal correspondence.

In general, patients with facultative divergent strabismus offer an opportunity for many interesting observations with regard to the visual act in strabismus.* In addition to the relationship between convergence and accommodation, which the patients may or may not have learned how to dissociate, there is a whole gamut of possibilities as regards the visual act. When these patients keep their eyes straight they may have normal binocular vision or an imperfect or even only rudimentary binocular coöperation. When their eyes are dissociated they show, as a rule, anomalous correspondence. It depends on the percentage of time during which these patients have a manifest strabismus, how deeply the anomalous

retinal relationship is rooted. Since most of them keep their eyes straight a good deal of the time, the anomalous correspondence is usually only superficially established. As a consequence, various phenomena pointing to the instability of the anomalous retinal relationship are frequently observed, such as a change in the retinal relationship with change in fixation.

With respect to the therapy I feel that these patients should always be operated upon, since they frequently have considerable eye fatigue, headaches, and difficulties in close work. Orthoptic exercises prior to the operation are unnecessary. The patients have excellent control over the position of their eyes and anomalous correspondence is usually only superficially established. Nor is it necessary to teach them how to dissociate convergence from accommodation, since they will not have to exert an undue convergence effort after successful surgery. Operation in these cases produces most gratifying and often spectacular results. The patients are relieved of their subjective symptoms; they are unable to dissociate their eyes any longer and, as a rule, soon acquire normal binocular vision. If necessary, this process can be hastened by postoperative orthoptic exercises. The operation of choice in uncomplicated cases is invariably some type of shortening operation of the internal rectus muscles.

4 Webster Avenue.

* Tschermak, to whom we owe much of our knowledge about anomalous retinal correspondence, has himself a facultative divergent strabismus and has reported his self-observations in a classical paper.¹ A case of facultative divergent strabismus, showing some similarities with the one presented here, was discussed earlier.²

SOCIETY PROCEEDINGS

EDITED BY DONALD J. LYLE

COLORADO OPHTHALMOLOGICAL SOCIETY

December 18, 1943

DR. C. A. RINGLE, *president*

QUESTIONABLE RETROBULBAR NEURITIS

DR. W. H. CRISP reported that Mrs. B. S. T., aged 27 years, complained on December 5, 1943, of failing vision in her left eye to such an extent that only the upper half of objects was visible. She was seen again on December 8th, at which time the left eye was tender to palpation. There was also some soreness on movement of the eyeball. She had had a cold which affected the left side of the nose particularly. The vision of the left eye was reduced to ability to see light. The pupil reacted very slightly on direct illumination, although indirect reaction was good.

Examination of the nasal cavity, sinuses, and throat was entirely negative. Neurologic examination showed no signs of systemic disturbance except for some slowness and fatigability of the abdominal reflexes, which sometimes is a very early sign of multiple sclerosis.

The patient was given 30,000,000 typhoid-paratyphoid by intravenous injection on December 9th, and 40,000,000 on December 14th. Good febrile reaction was obtained each time.

The pupil had become somewhat more active. The vision of the left eye improved slightly although limited to the upper half of the field. The left eyeball was no longer sore on pressure.

Discussion. Dr. Leo Davis said he thought that this patient had a possible retrobulbar neuritis, probably a result of the cold infection.

QUESTIONABLE DETACHMENT OF THE RETINA

DR. C. E. SIDWELL said that C. L. M.,

aged 35 years, sustained a penetrating injury to the left eye while using a hammer and chisel. There was considerable hemorrhage into the anterior chamber. Some vitreous escaped through the wound, which was on the nasal side behind the ciliary body.

The foreign body was localized and removed through the wound. The vision was 20/60 after removal of the foreign body but continued to fail until the patient was able to see only light. The iris was bound down by dense adhesions.

COMPLETE ATTENUATION OF RETINAL VEINS WITH MARKED NARROWING OF ARTERIES

DR. JAMES M. SHIELDS reported that Mr. F. H., aged 44 years, suffered a blow to the right side of his head in October, 1943, when a tractor he was operating in Honduras was involved in an accident. He also sustained injury to the side of the abdomen, and both legs were badly lacerated. He disregarded the injuries at the time but about five days later he appeared at the Infirmary and complained that the right eye was red and painful. The eye was examined and the conjunctival sac was irrigated.

The following day the patient complained of a cutting sensation in the right eye. Treatment consisted of the use of castor oil in this eye. Within a few days the vision of the right eye began to fail. He was told that this resulted from the use of castor oil. The patient was transferred to a hospital in Los Angeles and a diagnosis of iridocyclitis, right eye, was made. A careful search for a possible focus of infection was made, and tonsillectomy was advised. The Wassermann test was negative. Treatment consisted of salicylates and atropine instillations.

When the patient was seen again there

was no conjunctival nor pericorneal injection. The pupil was round and fully dilated. The eyeground showed no veins, only what were thought to be venous walls, which showed as white streaks. The arteries were small and showed no light streaks. The visual field was reduced to a small area on the temporal side; there was no central vision. Visual-field examination was made by use of the Finnoff transilluminator.

Two months had elapsed since the onset of the condition. There probably had been absorption of the hemorrhage usually seen in venous thrombosis. The cherry-red spot, seen in the macula in arterial obstruction, had evidently disappeared. The onset of blindness was gradual, as is frequently observed in venous obstruction.

OCULAR INJURY

DR. C. O. EIGLER reported the case of R. W., aged 14 years. On May 22, 1943, while at play, he was accidentally struck in the right eye by a BB shot. The shot struck the cornea below the center but did not penetrate the eye. There were hemorrhage into the anterior chamber, partial dislocation of the lens upward, and an iridodialysis below.

The eye remained quiet and there was no pain. The vision R.E. was 5/60. Treatment consisted of atropine instillations and hot compresses.

Discussion. Dr. John C. Long said he thought that the iridodialysis should first be repaired and then the lens removed or needled.

ACCIDENTAL GUNSHOT WOUND

DR. W. A. OHMART reported the case of S.K., aged 14 years, who suffered multiple gun-shot wounds to the arm, shoulder, and right eye in a hunting accident, on November 23, 1943. One shot penetrated the right eye at about the 1-o'clock

position, just outside the region of the ciliary body.

A conjunctival flap was made, closing the wound. The usual postoperative treatment of atropine, cold compresses, tetanus antitoxin injection, and later foreign-protein therapy, was instituted. It was very difficult to see the fundus, however, because of vitreous hemorrhage. The lens appeared clear.

X-ray report revealed that there were seven particles of shot in the region of the right side of the face anteriorly. Only three of these were possibly capable of having damaged the right eyeball. Two of them were apparently within the right orbit just beneath its roof. None of these was so situated as to be within the eyeball. It was not believed that any one of them had entered the cranial cavity.

The problem encountered was what type of future treatment would be most beneficial.

Discussion. Dr. W. H. Crisp said he thought it advisable to use conservative treatment in an attempt to save the eye.

GLAUCOMA

DR. DONALD H. O'ROURKE presented the case of Mr. J. F. Y., aged 42 years. The left eye had been enucleated 2½ years ago. A brief history of the left eye follows:

In June, 1940, the patient had had an acute attack of glaucoma. He was admitted to the eye service of one of the mid-western hospitals. Permanent operation on the left eye was deferred because it was recognized that there were extensive chorioretinal changes in the right eye. Consequently 12 paracenteses of the anterior chamber were performed during a period of three months. Finally a fistulizing operation (the type could not be determined) was attempted, which resulted in failure, and ultimately enucleation was necessary.

In addition to the chorioretinal changes in the right eye, some of which involved the macular area, the patient had a chronic simple glaucoma. The tension was 41 mm. Hg (Schiøtz). The vision was 20/50 with +1.00D. cyl. ax. 180°.

This patient was presented to illustrate two points: First, that undoubtedly the procrastination in operating on the left eye, resorting to numerous paracenteses instead, was an unsound surgical approach to the problem.

Second, this case presented the necessity of determining whether the progressive loss of vision in the right eye was due to the chorioretinal changes with some minute hemorrhages in the macula, or to the elevation in tension, or both.

Careful central-field studies, frequent recording of the intraocular pressure, and hospitalization for careful physical check-up were instituted.

While the patient's general medical possibilities were being studied the tension in the right eye responded to 1-percent pilocarpine used four times a day. The tension taken on several occasions was from 17 to 20 mm. Hg (Schiøtz).

These findings may delay, but only temporarily, operation on the eye.

Walter A. Ohmart,
Secretary.

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

December 14, 1943

DR. J. W. MCKINNEY, *presiding*

SARCOMA OF IRIS

DR. E. C. ELLETT reported two cases of sarcoma of the iris:

The first patient was D. H., a man, aged 56 years, who was seen in consultation in April, 1943. He had had several

attacks of pain and inflammation in the left eye for the past two weeks. The right eye was normal. Vision in the left eye was normal. The lower part of the iris from the 5- to the 7-o'clock position was thick and gelatinous looking. Vessels were seen in the growth and on the surface. The iris was involved from the pupil as far back as could be seen. The tension was normal. The eye was otherwise normal. Enucleation was performed. The growth was a malignant melanoma, spindle cell, subtype B.

The second patient, Mr. H., aged 53 years, was seen in consultation in July, 1943. He said that for 15 years he had had occasional hemorrhages in the front of the right eye which blurred his vision. The vision was normal. For three years he had noticed a yellow spot in the iris. There was a gelatinous mass involving the nasal half of the iris from the root to within 1 mm. of the edge of the pupil. This mass extended from the 2- to the 5-o'clock position. The tension was normal. The eye was otherwise normal. Enucleation was advised, but the patient did not return nor has it been possible to trace him. He had had the same diagnosis and advice a month before this examination.

A CASE OF SYMPATHETIC OPHTHALMIA WITH RECOVERY OF BOTH EYES

DR. E. C. ELLETT presented C. S., a boy aged 10 years, who was seen on March 27, 1928, and stated that on December 1, 1927, he had been struck in the left eye by a nail. The eye was penetrated but no foreign body remained in it. He received treatment and seemed to be recovering, but about two weeks before he was seen the vision began to blur in the right eye. The eye was painful but not sensitive to light. Both eyes showed some ciliary injection, no photophobia, and the tension of the left eye was questionably elevated to palpation.

R.E. The pupil was adherent all around, 4 mm. in size, and inactive. There was a thin film of deposit on the anterior capsule. A good reflex was obtained, but no details of the fundus could be seen. The vision was 20/70, somewhat improved by +2.50D. sph.

L.E. There was a corneal scar parallel to the limbus below, from the 5- to the 7-o'clock position. The pupil was oval and adherent. The iris showed several dark areas which protruded. These were atrophic spots, pushed forward by confined aqueous. X-ray examination was negative for foreign body. The condition appeared to be sympathetic ophthalmia.

Autohemotherapy was given, 7 c.c. of the serum injected. Atropine was instilled, and the patient put to bed. The eyes cleared, and on April 2d the vision was *R.E.* 20/20, *L.E.* 20/50, with correction. The fundus of the right eye was visible. The tension was *R.E.* 6 mm., *L.E.* 16 mm. Hg (Schiotz).

On April 11th the vision of the right eye was reduced to the ability to see hand movements. The eye was red and painful. Iris bombé was present. The left eye was unchanged. Diphtheria antitoxin was given daily for a week in doses of 10,000 units. On April 18th, the vision of the right eye was 20/200. The condition did not change during the summer. In October the right eye showed slight ciliary injection; the pupil was small and filled with exudate; and the iris was pushed forward in several spots. The left eye had not changed. In July, 1929, the vision was: *R.E.* 20/50 and J12; *L.E.* 20/30 and J1 with glasses. The eyes were white. Local treatment, which had been continued, was stopped.

In September, 1943, when the patient was seen for the last time, the vision was: *R.E.* 6/18 and J12 with glasses; *L.E.* 6/9 and J1 with glasses. The right eye was white. The tension was normal. There

was one anterior synechia in, and a smaller one down and out. The pupil was active. There were many pale K.P. below. In the left eye there was an adherent leucoma below. The pupil was a vertical slit, but active. There was some deposit on the lens capsule.

This boy was seen by several consultants and opinions had differed as to whether the left eye should be removed. Some advised it, but it seemed to offer his best chance for vision, and was retained with the present happy result.

GLAUCOMA WITH UNUSUAL VISUAL FIELDS

DR. PHILIP M. LEWIS presented B. C., a colored man aged 74 years, who had first been seen a few days previously because his vision had been failing for a period of three years. It had recently become very difficult for him to get about without stumbling over things. The vision was reduced to 10/200 in each eye with glasses. The eyes were free from congestion, and the pupils reacted sluggishly. There were early central opacities of both lenses. The tension was 45 mm. Hg (Schiotz) in each eye, but the discs were not cupped. They were rather pale, and the retinal vessels showed considerable sclerosis. No hemorrhages nor other abnormalities were found in the fundi. The visual fields were reduced almost to the point of fixation, the left slightly narrower than the right. The general physical condition was satisfactory, blood pressure was 180/100, the blood Wassermann test normal, and X-ray pictures of the skull and sella turcica normal. The intraocular pressure had remained high in spite of treatment with pilocarpine, eserine, and prostigmine.

Comment. While glaucoma may cause marked concentric contraction or "gun-barrel" visual fields, they are rather unusual. If they were due to increased intra-

ocular pressure, the discs would certainly show some cupping. It was thought that in this case the poor vision and contracted fields were due to neither the glaucoma nor the incipient cataracts, but to changes in the occipital lobes that were probably vascular in origin. It was felt that operation to reduce the intraocular pressure was necessary but, because of the contraction of the fields, was extremely hazardous.

PROGRESSIVE EXOPHTHALMOS OF UNKNOWN ETIOLOGY

DR. PHILIP M. LEWIS presented Mrs. L. N. R., who was first seen in July, 1943, with what was considered an allergic edema of the eyelids. There was no suggestion of exophthalmos. She was advised to omit all cosmetics temporarily, avoid smoke and dust as much as possible, and to watch her diet carefully. When seen again in September there was a definite protrusion of both eyes, the right measuring 19 mm. and the left 20 mm. The orbital tissues were tense and the globes could not be pushed back into the orbits. The lids were edematous and the retinal veins engorged, but there was no papilledema. Two basal metabolic tests had been made and were normal. Her physician reported that her general physical and laboratory examinations were normal. On the suggestion of Dr. Eustis Semmes, who also saw the patient, she had been sleeping with the head of her bed elevated and taking iodides internally. The exophthalmos had increased about 2 mm., but the lids still covered the corneas adequately. X-ray therapy of the orbits and the Naffziger operation have been considered.

REMOVAL OF INTRAOCULAR FOREIGN BODY FOLLOWED BY HEMORRHAGE

DR. PHILIP M. LEWIS reported the case of B. E. M., a white man aged 29 years,

who was struck in the left eye with a piece of steel on August 24, 1943. When first seen, two days after injury, the eye was only slightly inflamed and the vision was 20/30. There was a wound through the lower lid near the lower punctum. There was also a vertical wound through the conjunctiva and sclera in the 7-o'clock position, 8 mm. back of the limbus. The anterior segment of the eye was normal. There was a little blood in the vitreous and a large foreign body could be seen in the upper temporal quadrant, near the equator in the 2-o'clock position. X-ray pictures confirmed this location.

The steel was removed easily on the first application of the magnet to a meridional incision through the sclera at the equator in the 2-o'clock position. Surface diathermy was applied to the sclera of that area before closing Tenon's capsule and the conjunctiva. The following day the vitreous was rather hazy, but the fundus could be seen faintly. But the next day the vitreous was so filled with blood that no fundus reflex could be obtained. For three weeks the eye has remained in the same condition. The steel particle measured 3.5 by 2 by 1 mm.

This case was reported to provoke a discussion as to why this hemorrhage occurred, how it could have been avoided, what treatment if any was now indicated, and what was the prognosis. Should the steel have been removed by the anterior route or was the technique used faulty?

EPISCLERITIS AND SCLERITIS

DR. ROLAND H. MYERS presented R. B., a white man aged 55 years, who was first seen in the John Gaston Out-Patient Department on October 24, 1942, with a history of failing vision for the past few months. The vision at that time was: R.E. 5/200, L.E. 20/200. A diagnosis of immature cataracts with myopia was made. On October 6, 1942, an extra-

capsular extraction of the right lens was performed. In April, 1943, a peripheral iridectomy and an intracapsular extraction were done on the left eye. On May 10, 1943, the patient entered John Gaston Hospital with chills and fever. Blood smear was positive for tertian malaria. When discharged from the Hospital on May 12, 1943, he had some conjunctival injection in each eye, with discomfort. He was seen the following day, complaining of severe pain in the left eye. Examination of the left eye revealed a tender globe, and the lateral side from the 1- to the 5-o'clock position was a cherry color. The pathologic process was considered to be an episcleritis, and the patient was placed on dionin 5-percent thrice daily, hot applications, and aspirin compound for pain. After three weeks there was no improvement; then salicylates in heavy doses were given, and X-ray therapy of 150 units. The eye continued to be very painful, and the process increased to involve the eyeball from the 1- to the 7-o'clock position. The patient was sent to the Hospital.

General physical and laboratory tests were essentially negative, the Kahn test negative, X-ray studies of gums negative, prostate gland normal, tuberculin test weakly positive. The following treatment was given: hot, moist applications for 30 minutes, thrice daily, followed by atropine ointment 1-percent, and 3 injections of 10 c.c. of sterile milk at 4-day intervals. Very little reaction was obtained from foreign protein. During the Hospital stay, dionin, thyroid, and heavy doses of salicylates were tried, but no results were obtained. Opiates were often needed for the relief of pain. During his stay in the Hospital, a dark discoloration appeared under the conjunctiva at the 3-o'clock position, and gradually enlarged until it reached to 12 o'clock.

On September 1st, O.T. tuberculin was

started. The initial dose was tuberculin O.T. 0.25 mg. of dilution No. 2. The entire conjunctiva and sclera were red, and the eye painful. A necrotizing process appeared to be in progress in the upper temporal quadrant. Because of the very weakly positive tuberculin test, large therapeutic doses were given. Increasing doses were given subcutaneously every five days until a dose of 10 mg. was reached. Response to the tuberculin was immediate and by the time the No. 3 dilution was finished the pain had subsided, and the eye was clearing. When last seen the eye was comfortable and practically free from congestion. Where the inflammation had been most severe the sclera was now thin and atrophic, so that the characteristic blue color from the underlying uveal tract was quite noticeable. He was still receiving 10 mg. of tuberculin every two weeks.

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

January 11, 1944

DR. ROLAND H. MYERS, *presiding*

BLOOD STAINING OF THE CORNEA

DR. RALPH O. RYCHENER presented D. S., a boy aged nine years, the cornea of whose left eye was blood stained. On November 14, 1941, the boy had been struck in the left eye with a missile thrown by another youngster, and was treated elsewhere for three weeks with atropine and bed rest. On December 7th, there was blood staining of the cornea of the greenish-gray type with a clear zone at the limbus, giving slightly the appearance of a lens dislocated into the anterior chamber. The tension was elevated, and eserine was prescribed. There was gradual improvement in the resorption of the corneal stain, and two years later there was only a high

central fibrotic area of corneal scarring. However, there was almost complete absorption of the iris, and the ocular tension varied between 35 and 48 mm. Hg (Schiotz). The vision was reduced to ability to see light. A partial traumatic cataract was present.

It was deemed advisable to lower the pressure surgically in order to retain a good-looking eyeball, and, because of the traumatic aniridia, cyclodialysis was considered the operation of choice. This was performed on November 26, 1943, but was followed by hemorrhage into the anterior chamber, increased intraocular pressure, and secondary blood staining of the cornea. Paracentesis allowed evacuation of some heavy black clot and relieved the oculocardiac symptoms. The prognosis remained undetermined.

INTRACORNEAL HEMORRHAGE

DR. RALPH O. RYCHENER reported a case and exhibited a kodachrome slide of hemorrhage into the cornea, complicating a violent interstitial keratitis of luetic origin.

Mrs. A. E. W., aged 44 years, under treatment for syphilis, was seen on March 31, 1941, with an early interstitial keratitis of the right eye. A vascular fringe invaded the cornea from above, the epithelium was edematous, and a dirty-gray, plastic membrane was adherent in many places to the endothelium. The pupil was miotic but dilated to cocaine and atropine. Following the instillation of a single drop of dionin, there was a marked conjunctival reaction associated with hemorrhage from the vessels invading the cornea, causing an area of intracorneal hemorrhage measuring 2 by 4 mm. along the limbus above. This was well absorbed in 24 hours and entirely gone after 48 hours. Blood staining of the cornea is due to an absorption of blood-pigment products from an adjacent

subconjunctival or anterior-chamber hemorrhage. True hemorrhage into the cornea can come only from invading blood vessels.

HEMORRHAGE INTO THE LENS

DR. RALPH O. RYCHENER reported a case and exhibited a kodachrome slide of hemorrhage into, or blood staining of, the lens. Mr. S. H., a colored man aged 58 years, had been struck in the left eye while cutting wood. When he was seen one week later, the eyeball was red, the anterior chamber deep, a few posterior synechiae were visible, and there was massive hemorrhage into the vitreous. Atropine and aspirin were prescribed.

Seven months later the vision was reduced to perception of moving objects, and the pupil dilated roundly. Mature traumatic cataract with an inferior quadrant of subcapsular violaceous blood staining or hemorrhage into the lens was present. Apparently a rupture of the lens capsule on the inferior or posterior surface had occurred by contrecoup. The patient was not seen again.

SPONTANEOUS HOLE IN THE RETINA WITHOUT DETACHMENT

DR. RALPH O. RYCHENER said that Mrs. C. C. C., aged 58 years, had been observed for three years following a spontaneous hole in the retina without subsequent separation. For a month prior to December 16, 1940, she had been conscious of floating spots before the left eye. On that date her vision with correction was 6/6. Vitreous hemorrhage was present which apparently originated from a retinal hemorrhage far out and up at the third branching of the superior temporal vein, where a fresh hemorrhage overlay a venule. Two weeks later the hemorrhage had cleared, but a crescentic tear with a trapdoor tongue was visible in the retina at the original site of the hemorrhage.

The extent of the area involved was approximately one-half disc diameter. Eight days later the tongue had become detached and was visible in the mid-vitreous as a small, round operculum. Serous, subretinal elevation surrounded the hole, and the entire area then involved was the size of the disc. The eye was closely watched, but never thereafter was there any further evidence of separation.

Three months later the serous elevation seemed less marked and the edges of the retinal hole seemed flatter. After a year the retina was entirely reattached about the hole and since then it has been possible to view it only with some difficulty, since there now was scarcely any contrast between retina and exposed choroid. The visual acuity and fields were still normal.

LASHES IN ANTERIOR CHAMBER

DR. RALPH O. RYCHENER reported that R. C., a boy aged 6 years, had been accidentally struck in the left eye with a scissors point. He was seen 30 hours later, and there was a T-shaped laceration of the cornea just inside the limbus at the 3-o'clock position, with iris prolapse. The iris inside the chamber as well as out was covered by a dirty-gray membrane. The prolapse was excised, and an effort made to remove the plastic exudate covering the pupil. This was successfully done, although it was tenacious and of the consistency of old cyclitic membrane, and proved to include four eyelashes. The cornea was closed with intracorneal sutures, and sulfadiazine and foreign protein were administered.

Due to the resistance of the patient to any medication or examination, it was necessary to remove the sutures under general anesthesia. One month later the iris was drawn toward the wound with partial iris bombé. The eye was white but soft. The vision was reduced to light perception.

CORNEAL TRANSPLANTATION

DR. J. WESLEY MCKINNEY presented the case of R. S., aged 19 years, who was injured in 1926, in a furnace explosion. Both eyes were severely damaged; the left eye was removed four months later. The right eye recovered and retained good vision for a year and a half. The patient was then hit in the right eye and has since been blind.

When first seen in 1938, the vision was ability to see light. Then tension was 40 mm. Hg (Schiotz). The cornea was slightly edematous and showed a zonular opacity with calcium deposits which occupied the lower two thirds. The rest of the cornea was relatively clear. The anterior chamber was deep; the pupil was active and central; and the iris was tremulous. A red reflex could be seen in the pupil by directing the ophthalmoscopic light through the upper periphery of the cornea. No lens could be seen.

It was planned first to reduce the tension to normal and, if this were accomplished, to perform a keratoplasty to be followed, if necessary, by extraction of the dislocated lens. Consequently, a cyclodialysis was performed above, with some bleeding into the anterior chamber which cleared up rapidly. The tension remained normal for six weeks, when the eye became red and painful.

At examination, a shrunken cataractous lens was found in the anterior chamber; the cornea was edematous; and the tension 2+. In order to keep the lens in the anterior chamber until extraction could be performed, eserine was instilled repeatedly without appreciable contraction of the pupil. Aminglaukosan was then instilled, with marked constriction of the pupil behind the lens. A short Graefe knife incision was made above and enlarged with scissors, and the lens delivered with the aid of a broad spatula. The tension remained slightly elevated

for several months, necessitating a second cyclodialysis, which was performed down and temporally. This controlled the tension. Four months later a corneal transplantation was performed, with tissue from an eye enucleated for sarcoma of the choroid. The graft remained quite clear except during several bouts of increased tension which would cause edema of the graft. The fundus could be seen fairly well and showed widespread atrophy and pigment migration. The final vision was 3/200 for distance and 20/400 on the Lebensohn chart for near with the print held close.

The visual results obtained in this case could in no sense be called good, but this boy who had had only light perception in his remaining eye was now able to get about alone and to read large headlines in the paper.

MALIGNANT HYPERTENSION

DR. E. C. ELLETT reported that H. E. M., aged 65 years, who was seen on June 21, 1943, gave a history of failing vision in the left eye since May 3d, and in the right eye since May 4th. Examination showed a slight lens opacity in each eye and sclerosis of the retinal vessels. In the right eye the nerve was swollen two diopters. There were retinal hemorrhages and exudates and a tendency to a star figure at the macula.

THROMBOSIS OF THE CENTRAL RETINAL VEIN WITH SECONDARY GLAUCOMA AND RECOVERY

DR. E. C. ELLETT said that Miss H., aged 50 years, who was seen for the first time in May, 1932, had high blood pressure and had had a retinal hemorrhage two months before she was seen. The vision in the right eye was 5/60, left eye 6/6. The right eye showed an obstruction of the central retinal vein, and the tension was 50 mm. Hg (Schiotz). The

fundus was covered with large, dark, flame-shaped hemorrhages, radiating from the disc. The patient received general treatment from her physician, and pilocarpine drops were prescribed for the right eye. The tension declined, and in October it was 18 mm. In November the patient had a vitreous hemorrhage which obscured the fundus but did not disturb the tension. The vitreous cleared in about two months. This patient was seen at intervals, and in August, 1943, the vision in the right eye was about the same as it had been 10 years before. The tension was 16 mm. Hg (Schiotz). The blood pressure was 220/130. The fundus was dimly seen because of the lens opacity. There seemed to be no retinal hemorrhages, but there were many white patches. The left eye showed copper-wire arteries and arteriovenous compression, but the vision remained normal.

Dr. Ellett said that in his experience this was the only case of secondary glaucoma following obstruction of the central retinal vein in which recovery had taken place.

OBSTRUCTION OF A RETINAL ARTERIAL BRANCH

DR. E. C. ELLETT reported two cases as follows: Miss B., a nurse aged 37 years, was refracted in 1940 and again in 1942, and the vision in each eye was normal. In August, 1943, she gave for the first time a history of occasional blurring of vision of the right eye, which always cleared, but a few days before this visit it had blurred and remained blurred. The left eye was always normal. The vision was R.E. 3/200, off center. The media were clear but there was an area of retinal edema above the disc, and the superior branch of the artery seemed smaller than the inferior. A paracentesis of the anterior chamber was performed, and amyl nitrite given by inhalation. The

vision improved rapidly and was normal in three days. At that time, the edematous area was of better color and all the vessels were visible except the ascending nasal artery, which was concealed by the edema and appeared farther out, considerably constricted. The nerve was sharply outlined below, but blurred above. There was one linear hemorrhage at the lower edge of the edematous area. The patient had another short blurring spell two weeks later. Her general examination was negative except for a bad tooth, which was removed. Late in September, the vision was 6/6 and J1. The upper half of the nerve was pale, and the superior vessels were smaller than the inferior. The visual field of the right eye showed loss of the lower half from just below the fixation point.

Mrs. W., aged 42 years, a trained nurse and wife of a physician, was seen in August, 1942, complaining that she had been seeing fireworks in the medial side of her right eye for a month. She had had several blind spells in the right eye, especially on stooping or rising suddenly. Sometimes, only the upper nasal field would blur. The left eye was normal, the vision 6/6 and J1. The general physical examination was negative. The patient smoked cigarettes to excess. The right eye showed clear media, slight arteriovenous compression, and mild retinal edema above the disc. The disc was slightly swollen (about 1 diopter). The macula was normal. There was one retinal hemorrhage along the ascending temporal artery, 1 disc diameter from the disc, and up and in there were some fine white dots in the retina. The vision was normal. The patient was given amyl nitrite, and a paracentesis of the cornea was done, for it was thought that the retinal arterial circulation was impaired. She was given sodium nitrite intravenously daily for one week. After 10 days the

patient was seen again. She had had one blurring spell, and the retinal picture was unchanged.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

TWO METHODS OF GLAUCOMA SURGERY

DR. FRANK BURCH's motion picture on this subject comprised the first part of the instructional hour.

LACRIMAL-SAC OPERATIONS

DR. THEODORE S. BLAKESLEY's motion picture on this subject completed the instructional hour.

MODIFICATION OF THE CORNEAL SECTION IN CATARACT SURGERY

DR. JOHN H. BAILEY read a paper on this subject which has been published in the *Journal* (1944, v. 27, Nov., no. 11, p. 1253).

Discussion. Dr. George Epstein asked whether the healing period is prolonged with this section.

Dr. Daniel Rolett stated his belief that half the success of a cataract operation depends on a proper corneal section. He has devised a knife which makes, with a single sweep, a corneal incision of any size, the knife barely penetrating the anterior chamber. Details will be published shortly.

Dr. Sigmund Agatston inquired whether this method of making the section is not time-consuming.

Dr. Bailey replied that healing time is shortened and that while at first his method of making the section does take longer, experience permits greater speed. One of the advantages is the reduced danger of loss of vitreous, because each portion of

the flap is sutured before the next one is begun, and there are three smaller openings, temporarily closed prior to removal of the cataract, instead of one large opening.

INTRANASAL DRAINAGE FOR CURE OF CHRONIC TEAR-SAC INFECTION

DR. DAVID MORGENSTERN believes that enlarging the opening in the tear sac to the same size as the bony opening is the greatest difficulty in any intranasal technique for cure of chronic tear-sac infection. To surmount this difficulty, particularly when the sac is scarred or thickened, it is fully opened first by a transcanalicular incision.

By placing the forefinger over the tear sac, one can feel the bony margin surrounding it as well as an instrument inserted into it either through the canaliculus or through the nasal cavity. Under the guidance of the palpating forefinger, a thin knife passed through the dilated canaliculus cuts an inverted U-shaped incision in the tear sac against the firm backing of the bony lacrimal fossa. A probe is then pushed through the lacrimal bone into the nasal cavity to guide increasingly larger operating hooks, ends bent at 90 degrees, which are slid along this probe through the bone into the sac. Palpating with the forefinger of the free hand at the inner canthus, the operator feels for movement of the largest hook used last. Under guidance of touch, the bony lacrimal fossa is completely broken down. An inverted U-shaped flap is thus freed from its bony attachment. Saline irrigations turn this flap down into the newly formed bony opening.

To combat closure as well as to reduce infection, a large hook, insulated except at its bent end, electrocoagulates the bony opening and the tear sac. The current is applied lightly where the flap has been turned down. This flap helps safeguard

the permanence of the bottom of the bony opening and aids in epithelization.

Since there is a minimum of tissue destruction and bleeding, this procedure is performed in the office, the patient leaving after a short rest.

Discussion. Dr. Benjamin Easterman asked how cauterization of the sac is avoided and how stricture due to cauterization of the canaliculi is prevented.

Dr. John H. Bailey inquired whether Dr. Morgenstern had experienced closure of the opening.

Dr. Morgenstern said he found that palpation of the electrode indicates its position and locates the area to be cauterized. If inadvertently an undesired area is cauterized, passage of a long bent needle through it into the bony opening combats possible stricture. Irrigation every 10 days will maintain patency.

The initial placement of a flap at the bottom of the bony opening safeguards against closure of the aperture, but if there is narrowing or a tendency to close, recoagulation will correct it.

Leon H. Ehrlich,
Secretary.

CHICAGO OPHTHALMOLOGICAL SOCIETY

January 17, 1944

DR. VERNON M. LEECH, *president*

CLINICAL MEETING

Presented by the Department of Ophthalmology, University of Chicago

PROGRESSIVE NUCLEAR EXTERNAL OPHTHALMOPLÉGIA (GOWER AND VON GRAEFE)

DR. WILLIAM ROSENBERG presented F. G., a woman aged 37 years, who was seen for the first time on September 16, 1943, with a complaint of drooping of the eyelids. Ptosis of the upper lid of the

right eye started when the patient was 14 years old. The lid of the left eye began to droop in January, 1943. At that time severe retrobulbar and occipital headaches began to occur about once a week, associated with an increase in the ocular symptoms. The family history was non-contributory.

No facial asymmetry was noted. The corrected visual acuity was R.E. 20/25; L.E. 20/20. The palpebral aperture of the right eye measured 5 mm.; that of the left, 3 mm. The eyes were parallel in the primary position, and there was great limitation in the range of extraocular movements in all directions. Pupillary reactions were normal. The accommodative mechanism was normal, as was the remainder of the ocular examination. Following the administration of 1 mg. prostigmine as a therapeutic test, no subjective nor objective improvement was noted. Routine laboratory tests gave normal reactions. Neurologic examination revealed nothing further. The treatment was of nonspecific nature.

TRAUMATIC SCLERAL RUPTURE AND RETINAL DETACHMENT

DR. WILLIAM ROSENBERG said that L. A., a woman aged 26 years, was seen on September 9, 1942. She stated that she had struck her right eye with a cosmetic brush two weeks before. She had had mild pain and almost immediate blurring. The vision was R.E. 20/100; L.E. 20/13-4.

Examination revealed a huge temporal disinsertion which extended from the 7- to the 11-o'clock position. The patient was admitted to the hospital and remained at absolute bed rest until September 11th, when a microcoagulation operation was performed. Although the operative reaction was satisfactory, the retina remained elevated in the periphery and the disinsertion did not flatten. On September

25th, five microcutting perforations were made in the sclera and the lower temporal quadrant in an attempt to release subretinal fluid. The patient was discharged on October 8th, and followed in the out-patient clinic. The retina remained elevated temporally, although excessive chorioretinal scarring was noted. The vision was 20/100.

The patient was readmitted to the hospital on November 15th for further surgery, and the following day it was noted that an arcuate scleral rupture was present, parallel to and 8 mm. from the limbus, lying under the inferior; and external-rectus-muscle bellies and extending from the 5:30- to the 10-o'clock position. This rupture was sutured and several cutting diathermy punctures were made in the inferior temporal quadrant to permit escape of a moderate amount of subretinal fluid. Visual acuity improved to 20/40, but there was little improvement in the field of vision; the retina still appeared elevated, although there was no apparent motion on movement of the eye.

The retina remained attached and considerably flattened, although there was slight elevation beyond the line of diathermy application. On December 9, 1943, vision was R.E. 20/30+3; L.E. 20/16. The patient had resumed her normal activities and had noted no further difficulty.

ESSENTIAL ATROPHY OF THE IRIS, BILATERAL

DR. WILLIAM ROSENBERG said that R. T. M., a 10-year-old boy, came to the Clinic on November 10, 1943, complaining of poor vision in each eye since birth. Corrected vision was R.E. 20/30+1; L.E. 20/50+2.

Examination revealed essentially smaller corneas than normal; each measured 9 by 9 mm. The slitlamp showed bilateral extensive scarring, stretching, and atrophy of the irides with shallow chamber

angles, obliterated in places by anterior synechiae. There were many posterior synechiae and pigment proliferations, and many iris holes and pigment deposits on the lenses. The fundi appeared normal. Bjerrum fields, with 3/1000 isopter, were normal. The tension was R.E. 26.5 mm.; L.E. 20.5 mm. Hg (Schiotz). With the Soutter tonometer the tension was 24 and 26 mm., respectively. It was felt that congenital iris colobomata might have been present at birth but that these were now masked by the extensive pathologic changes; or that the changes might have been secondary to prenatal ocular inflammation.

METASTATIC MENINGOCOCCIC ENDOPH- THALMITIS

DR. WILLIAM ROSENBERG presented J. W., a girl aged 18 years, who had recovered from meningococcic meningitis. Treatment had consisted of anti-meningococcic serum and sodium sulfadiazine in adequate doses. Atropine sulphate, homatropine, and hot compresses were used on the eyes irregularly.

On examination, the vision was ability to see hand movements at about 3 feet in each eye. There were dense exudative masses lying behind each lens. Typhoid-fever therapy was instituted, and atropine sulphate was instilled in each eye every 3 hours. Penicillin administered by iontophoresis was given for 25 days, with slight improvement in the right eye within 8 days. After 16 days there was definite evidence of recession of the pathologic process in the right eye, but not in the left, although there was some subsidence of the inflammatory reaction. Improvement continued gradually, and on December 29th, the vision was R.E. 20/30—3; L.E. ability to see hand movements at 3 feet. Light projection was accurate with the left eye, with satisfactory red and green perception.

TUBERCULOUS IRITIS, BILATERAL

DR. BARBARA SPIRO presented C. C., a Filipino aged 45 years, who had been seen in October, 1942, and who gave a history of failing vision for several months, associated with continuous headaches. The vision was R.E. 20/50; L.E. 20/30, with correction. There was evidence of severe bilateral iritis with almost complete posterior synechiae. Laboratory tests gave negative reactions, and biopsy examination of a lymph gland showed only nonspecific chronic inflammatory changes. Under treatment with foreign proteins and vasodilators the vision gradually improved and, following typhoid-fever therapy in November, refraction under cycloplegia revealed vision of 20/16 in each eye. A satisfactory examination of the fundi was then possible. Pigment clumping and rarefaction of choroidal pigment were noted as well as vitreous floaters in the left eye. Following a course of old tuberculin, starting with .0001 mg. and increased to 2.5 mg., he remained free of symptoms of uveal activity. Biopsy specimen of an enlarged lymph gland in October, 1943, again showed nonspecific chronic inflammatory changes, but tubercle bacilli were found in smears from an inoculated guinea pig.

KAYSER-FLEISCHER RING OF THE CORNEA IN HEPATOLENTICULAR DEGENERATION

DR. BARBARA SPIRO said that S. R., a white man aged 32 years, had a diagnosis in 1940 of Wilson's hepatolenticular degeneration. One year later a typical Kayser-Fleischer ring was found when he was seen in consultation in the Eye Department.

SYMPATHETIC OPHTHALMIA

DR. BARBARA SPIRO presented J. O., a white man aged 64 years, shown before this Society in 1941 and 1942, as a histo-

logically proved case of sympathetic ophthalmia, occurring 25 years after the original injury. The sympathogenic right eye was removed in 1941, when the left eye began to show signs of acute inflammation. Following enucleation the patient was treated with cycloplegics locally, sulfonamides by mouth, and mapharsen intramuscularly. For 23 months there followed a course of slowly subsiding activity in the left eye. There had been no activity for the past six months, and therapy was stopped eight months ago. Corrected vision was 20/20.

BILATERAL CENTRAL CHOROIDITIS

DR. MAURICE J. DRELL presented I. C. D., a white woman, aged 62 years, who said that since May, 1943, there had been progressive diminution in vision, with metamorphopsia. Vision with correction was 20/100 in each eye. General physical examination was negative except for mild arteriosclerotic changes and bilateral macular disease. The foveas were replaced by funnel-shaped excavations at the bottom of which was seen red mottled choroid with scattered whitish plaques. Surrounding the foveas was a doughnut-shaped area of mild edema. Campimetry disclosed a central scotoma on each side with the 1/1000 white target.

BILATERAL HYPERTENSIVE RETINOPATHY FOLLOWING TOTAL SYMPATHECTOMY

DR. MAURICE J. DRELL said that M. J. W., an obese white man aged 42 years, was seen in August, 1943, following an attack of dizziness four days previously, at which time he noted diplopia and drooping of the upper lid of the right eye. Six months previously he had had a spontaneous subconjunctival hemorrhage of the left eye. Except for occasional headaches, no other symptoms were elicited.

The corrected vision was 20/16 in each

eye. The lid of the right eye drooped moderately. Fixation with the right eye was preferred, with a 20-degree divergence; with the left eye fixating, the divergence was 15 degrees. Motion of the right eye was limited in all directions except to the right and down. The pupil of the right eye was larger than that of the left, and reacted more slowly. The fundi showed bilateral marked hypertensive neuroretinopathy with papilledema, great arteriolar attenuation, spasms, exudates, and hemorrhages. The blood pressure was 190-200/150-165 mm. Hg.

As it was thought that the patient represented a medical emergency, sympathectomy was suggested. Six weeks after onset, while the patient was at bed rest awaiting surgery, the ophthalmoplegia cleared almost completely within a period of less than 24 hours. Smithwick sympathectomy was performed in two stages. Recovery was uneventful and the patient resumed his work six weeks after surgery. The blood pressure was then 110/84 when standing and 134/96 when recumbent. The external ocular movements were unrestricted. With the red-glass test there was separation of the images only when looking in the extreme left-and-up position of gaze. Hypertensive changes were still present in the fundi, but to a considerably less extent.

OCULAR TOXOPLASMOSIS

DR. MAURICE J. DRELL said that N. M. D., a white woman aged 26 years, had had glasses prescribed for a mild refractive error in October, 1942. No ocular pathologic change was noted. In August, 1943, she returned with a history of blurring of the vision of the left eye of 3 days' duration. The corrected vision was R.E. 20/13; L.E. 20/30, slowly. The right eye was normal. The left eye showed a C-shaped raised area of choroiditis, deep to the retinal vessels, butterfly in appear-

ance, and mottled with pigment disturbance, apparently made up of a number of smaller confluent foci, and enclosing the macula in the concavity of the C. Campimetry showed an absolute paramacular defect almost exactly duplicating the lesion. During the ensuing two weeks the lesion extended to include the macula. The vision of the left eye decreased to 20/200. During the following two months the lesion extended in spite of all therapy until it reached a size of 6 to 8 papilla-diameter radius about the disc. Many fine vitreous floaters appeared, and biomicroscopy showed innumerable fine pigment keratitic precipitates and a plus aqueous ray.

Extensive physical and laboratory examinations showed nothing of significance. Treatment consisted of atropine, nitrites (both orally and parenterally), proteolac, and a course of sulfathiazole. Finally the patient was hospitalized and given sulfadiazine and typhoid vaccine, with a rise in temperature to over 104°F. on three occasions. After the second of these, she showed subjective improvement and the vision improved to 20/70. Since then the vitreous has cleared, the pigment keratitic precipitates have practically disappeared, and the fundus lesion appeared to be inactive. The vision was 20/200. The rabbit-skin protection test for toxoplasmosis was reported at about the time of the typhoid injections.

The only history of contact is that chickens were kept in the yard of her downstairs neighbors. These had "colds" last summer, with sore eyes, and "tended to bury themselves in the ground."

OCULAR TOXOPLASMOSIS

DR. MAURICE J. DRELL said that D.N.C., a white man, aged 25 years, was seen in December, 1943, with a history of intermittent loss and return of vision.

During the attacks the patient saw moving brown spots before the eyes. There had been no other symptoms. He stated that a number of years ago he raised rabbits as a hobby.

Corrected vision was R.E. 20/50; L.E. 20/200. Many vitreous floaters were present. The fundi showed many heaped hyperpigmented and atrophic chorioretinitic patches (0.25 to 2 papilla-diameters in size) throughout the fundi, with involvement of both macular areas. There were also several bands of proliferating retinitis. Biomicroscopy showed a rare cell in the left anterior chamber. All laboratory and X-ray examinations were negative. The rabbit-skin protection test for toxoplasmosis was reported strongly positive.

OCULAR TOXOPLASMOSIS

DR. MAURICE J. DRELL said that B. B. S., a white woman aged 25 years, gave a history of poor vision in the right eye of 7 days' duration. On examination, the vision R.E. was perception of hand movements at 1 foot. There was a ciliary flush. Keratitic precipitates were grossly visible. The pupil of the right eye was irregular and larger than that of the left eye, and reacted slowly. The fundus showed a marked vitreous haze, through which could be seen a raised area of yellow-white exudative choroiditis surrounding the disc and extending past the macula. There were several small hemorrhages at its edges. Biomicroscopy showed many keratitic precipitates and many cells, and 2-plus aqueous ray, as well as posterior synechiae at the 2- and the 6-o'clock positions. On the Bjerrum screen an absolute right central scotoma of 10 to 20 degrees was elicited, extending outward to include an almost complete inferonasal-quadrant anopsia.

The synechiae were severed with sub-

conjunctival epinephrine. Local instillations of atrophine were given, and brewer's yeast was administered by mouth. Extensive etiologic investigations showed nothing of significance. There was a daily rise of temperature to 99°F. The red blood cell count fell from 4.78 on November 3d to 3.92 on November 29th. At that time, the toxoplasmosis rabbit-skin protection test was reported as strongly positive. Injection of the patient's blood into a mouse gave no results.

The eye continued to improve slowly; the anterior-chamber reaction was minimal, and the fundus showed a large white atrophic peripapillary chorioretinitic lesion with hyperpigmented margins. The only relevant feature in the search for a contact was that someone in the family had raised chickens, a number of which had died quickly during the summer.

AFFERENT STURGE-WEBER-OSLER-DIMITRI SYNDROME

DR. MAURICE J. DRELL presented G. C., a white man, aged 41 years, who had been seen intermittently for 10 years. A tentative diagnosis of migraine had been made by the neurologic service in 1939. In November, 1940, he reported a history of blurring of the vision of the right eye for 5 days. The fundus of the right eye showed several hemorrhages in the depth of the physiologic cup, and numerous tiny hemorrhages scattered throughout the fundus. The veins were tortuous, moderately dilated, with compression at the arteriovenous crossings. The arteries showed slight uniform increase in the central light streak, but no definite attenuation. The fundus of the left eye was normal. Campimetry of the right eye revealed a paracentral scotoma. The visual haze of the right eye varied in intensity for a few weeks and finally disappeared. The hemorrhages were absorbed over a

period of six weeks. General physical examination, complete hematologic study, and X-ray films revealed nothing significant.

The patient returned in December with a history of recurrence of blurring in the visual field of the right eye. The vision was 20/13 in each eye. The fundus of the right eye showed tortuous dilated veins and attenuated arteries. In the macular region was fine new-vessel formation with a tiny hemorrhage just beyond the terminal twigs of two of these vessels. Campimetry showed a relative sector-shaped paramacular scotoma lying between the fixation point and the blind spot. The tension had always been normal. All laboratory studies were non-revealing. A port-wine type of nevus was noted on the lower lip. The blurring was present intermittently for 10 days, then the vision diminished to 20/200, a few more hemorrhages were found, and a dense centrocecal scotoma was present. Three days later the fundus had the appearance of a partial central-vein thrombosis with perhaps complete occlusion of the superior temporal branch, showing papilledema, exudates and sheetlike hemorrhages in the region of the distribution of the superior temporal vein, and smaller hemorrhages throughout the fundus.

Since then the disc had become flat, hemorrhages and exudates had been absorbed, the vision slowly improved to 20/16, and the scotoma thinned out. Therapy consisted of nitrites, potassium iodide, vitamin-B complex, and citrus juices. Following the development of the picture of vein occlusion, atropine was given on three different occasions as a retrobulbar injection.

It is possible that the clinical picture fits into the phakomatosis group, postulating the presence of an angioma of the ophthalmic vessels, with each recurrence

representing the result of an embolic phenomenon.

SCIENTIFIC PROGRAM

CORNEAL DYSTROPHIES

DR. ROBERT VON DER HEYDT presented a paper on this subject which was published in this Journal (1945, v. 28, Jan., p. 55).

Discussion. Dr. Robert J. Masters said that corneal dystrophies have a tendency to follow patterns of development that fail to be typical. Even in familial hereditary granular type they may exhibit a varied appearance in the eyes of the same individual or in members of the same family.

In 1940, A. Pillat, in an article in the *Klinische Monatsblätter für Augenheilkunde*, described a familial corneal dystrophy characterized by peculiar central flaky and peripheral lattice-shaped opacities in both eyes of the same individual. The central changes were described as peculiar crumblike opacities deeply situated in the stroma, not in the shallow portion under Bowman's membrane. This patient's sister had the same condition, and there was a history of eye disturbance in the father and grandfather. One might believe that Pillat's patients had mixed in the two eyes two types of dystrophy, granular and lattice-shaped, according to the classification of Bücklers. Pillat felt sure that his patients exhibited a new type of dystrophy.

The term dystrophy means defective nourishment and can be applied to many types of nutritional disturbance of the cornea, of senile, inflammatory, or occupational irritative origin, or of the hereditary type with which the term is usually associated. Davidson suggested that corneal dystrophies be classified as senile, secondary, occupational, and hereditary. In the senile type he would

put arcus senilis; in the occupational type, long-continued irritation due to chemicals. Regarding Fuchs's epithelial dystrophy, it is difficult to explain why so many elderly people have so few epithelial dystrophies, unless there is some hereditary tissue tendency that predisposes the cornea to development of the changes which typify Fuchs's epithelial dystrophy.

There is no question but that the most profitable study so far as dystrophies are concerned comes from repeated examination. Dystrophies are bilateral; those of hereditary type are inclined to progress; they are avascular. Certainly it is important before undertaking a cataract operation to make a thorough examination with the slitlamp to ascertain the condition of all the ocular tissues including the cornea. This leads to the question as to the experience of others who have operated for cataract upon eyes which exhibited a corneal dystrophy. How did the eye heal and what, if any, complications developed?

Dr. Sanford Gifford recalled a patient with very marked dystrophy on whom an intracapsular extraction was performed. Following operation she developed what looked like Fuchs's epithelial dystrophy. This does not develop until the guttata lesions are so advanced that the aqueous gets into the cornea. The operation apparently put the finishing touch toward development of the condition.

Dr. Vernon M. Leech stated that Dr. Masters mentioned the importance of careful slitlamp examination prior to operation for cataract. Faint corneal opacities, especially early dystrophies, stand out fairly well with oblique illumination when the pupil is large and black, but are difficult to see when the background is gray from cataract formation. He recalled the case of a woman who had had cataracts diagnosed, and before she would permit examination except for a glance

at her eyes with oblique illumination, she insisted on a general discussion of cataract surgery. She was assured that there was nothing to worry about; that the results were preponderantly good, vision could be restored, and so forth. When examination was completed, including slitlamp study, a bilateral central dystrophy was found, which caused modification of the prognosis on her cataract operation.

Dr. Peter Kronfeld said that the incident reported by Dr. Gifford had been observed in at least three cases at the Illinois Eye and Ear Infirmary. In two cases the picture was that of marked cornea guttata; in the third beginning epithelial changes were superimposed upon the cornea guttata.

In a case of that type observed by Dr. Terry of Boston, and reported before the New York Society for Clinical Ophthalmology, he also raised the question of what to do with the other eye. If he performed a cataract extraction he would fear that the second eye would take the same unfortunate course as the first.

Dr. Robert von der Heydt, in closing, replied to Dr. Masters, in reference to Pillat's case, if Bückler's classification is accepted, each of his three types presents a definite clinical entity. No one type resembles another if carefully differentiated.

In the picture shown of the incipience, there were lesions under Bowman's membrane and within the stroma. The crumb-like pattern is seen throughout the stroma and at all depths. In Pillat's case the central area may have been somewhat similar. However, there were no lattice lesions. The lines were radical and only at the limbus.

With regard to cornea guttata, there are many senile and presenile persons having disseminated guttata spots in the corneal center. There must be many hundreds before the endothelium is involved. This layer is the barrier membrane between aqueous and corneal stroma. The guttata lesions must be extremely numerous to cause an epithelial dystrophy.

The postoperative condition which may develop and which resembles Fuchs's epithelial dystrophy is due to accidental trauma to the endothelium by instruments. We find a similar condition in birth injuries; there is a milkiess of the whole cornea such as seen in the early stages of interstitial keratitis. It is not due to the fact that Descemet's membrane has ruptured, but to the splitting of the endothelial layer. When it re-forms the barrier function returns and the corneal stroma clears.

Robert Von der Heydt.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to Dr. Lawrence T. Post, 640 South Kingshighway, Saint Louis 10, Missouri; Society Proceedings to Dr. Donald J. Lyle, 904 Carew Tower, Cincinnati 2, Ohio. Manuscripts should be original copies, typed in double space, with wide margins.

Exchange copies of medical journals should be sent to *Dr. William H. Crisp, 530 Metropolitan Building, Denver, Colorado.*

Subscriptions, applications for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio.* Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Miss Emma S. Buss, 5428 Delmar Boulevard, Saint Louis 12, Missouri.* Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Alhnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

DIRECTIVES FOR ETHICAL DISPENSING

In the February issue of this Journal the writer discussed the ethics of dispensing lenses. The editorial created some comment, hence he thought that further consideration of the subject might be profitable. He suggested that the Section on Ophthalmology of the American Medical Association define acceptable methods and he touched briefly on some of the practices now employed. It is perhaps worthwhile to enlarge somewhat upon different possibilities for dispensing glasses. But before doing so, it might be well to generalize a little. In the first place, there should be no idea in the minds

of anyone that the question is primarily one of integrity. It must be obvious that if an ophthalmologist desires to capitalize unscrupulously on his patient, he can do this in many ways other than by taking a profit on glasses. For example, he may be entirely ethical in his dispensing of glasses and still have patients make unnecessary visits to his office, or he can perform operations that are not needed. There isn't anything against the law in an eye physician's taking a major part of the profit from the sale of optical goods, though he might need a retailer's license to do so. The question is whether this practice is regarded by physicians as fulfilling the best ideals of the profession.

A second point is that a sufficiently broad concept is necessary to allow for the differences of practice in different localities, chiefly as concerns urban and rural areas. This may have for its crux rather the education of the public than of the doctor. Urban peoples have in general learned that the doctor's fee is largely for his opinion and advice, but in rural communities there is still a strong tendency for patients to think that they are paying for the medicine that they receive and not for the advice that they get. Likewise in small communities patients are far less willing to pay even a small fee for a refraction and a small amount for the glasses than to pay a bigger fee for glasses than for the other two combined. The necessity for the doctor to give something concrete in return for the patient's fee was so imbedded in the public mind that 30 years ago, even in large cities, some ophthalmologists made no charge if a new prescription was not given after the refraction!

The simplest method for the ophthalmologist is the one approved in the resolution passed by the Section on Ophthalmology of the American Medical Association in 1924, which indirectly endorses this method by stating that "we deprecate the selling of glasses by the ophthalmologist to his patients in communities where the services of reliable dispensing opticians are obtainable," namely that of referring his patients to a reliable dispensing optician. This method is surely above reproach if, by reliable we mean a nonrebating optician. The doctor makes a charge to the patient for his services to him and has no part in the financial transaction with regard to the glasses, though most opticians are glad to accommodate by charging less than the customary retail price to indigent patients on the doctor's request and by making any necessary changes in the

prescription for the doctor within a reasonable length of time. If the optician, as is sometimes the case, is willing to sell lenses on a doctor's prescription for less than the customary retail price, this also surely cannot be objected to since it reduces the cost to the patients and is a logical procedure, because the optician is relieved of the expense incident to his performing the refraction, if he be licensed to do so, or of employing someone to give this service. This method with the above modification should be endorsed by the Section.

Where such opticians are not available, the ophthalmologist should be permitted to dispense his own lenses and make a charge to the patient that would include his physician's fee plus a charge for the glasses sufficient to cover his overhead in dispensing them. This would seem to be as open a method as can be employed where there is no dispensing optician available, since it is quite possible to let the patient understand the elements in the charge so that there need be no hidden fee. Undoubtedly this method permits of as liberal an interpretation of overhead as the ophthalmologist sees fit, but here the assumption is that the physician is actuated by a desire to deal honestly with his patient and his obvious limit is the cost of similar glasses in his community. This method should be accepted as ethical.

A third possibility for those who do not care to undertake the necessary labor of fitting and adjusting glasses and of performing the other mechanical essentials in the dispensing of glasses is the employment of a technician to perform these functions and making a charge for the glasses sufficient to cover the additional outlay of the salary of this individual. This is essentially the same as number two and should be acceptable.

A fourth method is the employment of an agency which performs the functions

of dispensing for the physician, the entire financial transaction being handled by the physician who makes the charge to the patient for both his fee and for the glasses and pays the bill for the optical goods and services to the agent. If the ophthalmologist will reveal the expense elements in the transaction to the patient, there should be no objection to this practice.

A fifth method is that which has been discussed under "Agency dispensing" in a previous issue of this Journal. In this case the agency collects the fee for the cost of the glasses, which within certain limits is specified by the doctor, and returns any surplus to the doctor at the end of the month or charges his account with any deficit. The writer believes that this almost surely entails a hidden fee and that the ophthalmologist cannot exercise adequate control over the cost of the glasses to the patient, or, broadly speaking, over the entire transaction and he thinks that this method should not be approved.

A sixth manner of handling glasses is through a company owned and controlled by one or more ophthalmologists, perhaps as a stockholders' corporation. There are several such concerns under the control of well-known and respected ophthalmologists. By them they are undoubtedly conducted ethically and without profit to the doctor from the business of handling merchandise. In such circumstances the cost of glasses to the patient can probably be reduced materially and excellent service given. The possibilities of entering into a business for profit in this arrangement is certainly ever present and its acceptance as an approved procedure should be contingent upon the willingness of those engaged in the project to permit of scrutiny of the business by whatever body is responsible for the medical ethics of the community.

Finally, the practice of referring a patient to an optician who returns a percentage to the ophthalmologist merely for referring the patient to him needs no comment.

The writer again urges that the Section of the American Medical Association study the matter anew and present some positive directives on the subject of the dispensing of lenses.

Lawrence T. Post.

PROFESSIONAL CLAIMS BY BRITISH OPTICIANS

The controversy as to who should have legal right to test and prescribe for refractive errors is likely to live a long life. There are some ophthalmic physicians who would prohibit entirely the prescription of correcting lenses by refracting opticians; and, on the other hand, there are "optometrists" who would permit medical practitioners to undertake refraction only after passing a special examination to show their proficiency in the subject.

It may be remarked that the use, in the preceding paragraph, of quotation marks around the word "optometrists" is justified by the fact that, according to the meaning of the French word from which the title was borrowed, anyone who measures the refraction of the human eye is an optometrist, whether his right to do so rests upon medical or a nonmedical basis. The word is not employed by British opticians, and does not appear to prevail in any of the British dominions or colonies outside of Canada and Newfoundland, which have of course been influenced by contiguity to the United States. "Refracting optician" would be much more accurately descriptive and much more intelligible to the general public, although perhaps less in

harmony with the ultimate professional ambitions of those who coined the word "optometry." In Great Britain the expression "optical practitioner" seems at present to lead the field, although it might of course be used just as well by the grinder of lenses or by what is known in this country as the "prescription optician."

The recent tentative scheme of the British Government (not yet passed into law) for a complete nationalized health service led to the creation by British opticians of a special committee, called "The Beveridge Report (ad hoc) Committee (Optical Profession)," which in due course published a carefully reasoned report on the controversial issues involved as between the medical profession and the optician. This report, although now over a year old, is not perhaps familiar to most American ophthalmologists, and a summary of its arguments may possess value for many of our readers.

Parenthetically, as regards the optical problem, it is well to remember the effect of constitutional differences between Great Britain and the United States. In the United States, legislative experiment is favored by the existence of an independent legislature for each state; whereas in Great Britain the privileges of local self-government are from time to time delegated by the national government to local bodies such as the county councils and municipal authorities. Thus the decision whether to give official recognition to "optical practitioners" has rested in the hands of the central government.

Attempts made by the optical practitioners, in 1906 and 1927, to introduce a system of state registration were defeated, partly because the British Parliament showed little inclination to concern itself with the proposal, and partly because of very strong opposition by the medical profession. The parliamentary bill intro-

duced for the opticians in 1927 was studied by a "Departmental Committee," which we are told based its recommendation against the bill upon "the medical profession's promise that an efficient and comprehensive ophthalmic service would be available within a reasonable time."

British opticians have a sort of semi-official recognition in the fact that they have coöperated in the establishment of a register of optical practitioners whose work is accepted under the National Health Insurance administration. But the medical organizations of Great Britain have declined to participate in this arrangement, which is handled by a body called the "Ophthalmic Benefit Approved Committee," and in which the old mutual insurance organizations play an important part.

Five organizations, the British Optical Association, the Worshipful Company of Spectacle Makers, the Institute of Chemists-Opticians, the National Association of Opticians, and the Scottish Association of Opticians, conduct periodical examinations and issue diplomas as to proficiency in optical practice. These diplomas conform to a standard specified by the "Ophthalmic Benefit Approved Committee." The examinations cover theoretical and practical optics, subjective and objective methods of measuring refractive errors, optical apparatus including the testing of visual fields, anatomy and physiology, orthoptics, such knowledge of abnormal and pathologic conditions of the eye as is necessary for referring the patient to a physician, and lens grinding and fitting. In certain parts of the British Empire such an optical diploma "entitles the holder to admission to the state registry," although he has no such privilege in Great Britain.

The examination papers of one of the optical organizations, The Institute of Chemists-Opticians, are set, we are told,

under the supervision of the officials of the University of London. The optical Beveridge Report Committee quotes two ophthalmic surgeons, themselves examiners, as speaking highly of the standards of the examinations conducted for several of the optical organizations.

Opinions quoted from one of these ophthalmic surgeons (Tibbles), as given in the report, were expressed by him seven years ago in a letter to the British Medical Journal. This letter contained other statements of interest to students of the British situation. Tibbles asked, for example: "What is to become of the eye surgeons in the future, as they cannot possibly live on the small percentage of cases of diseased eyes, and at present the national health insurance patients, who form a big proportion of the population and formerly paid us fees themselves, are now sent to the optician, who can refer them to us if he thinks fit?" The other ophthalmic surgeon quoted is Lindsay Johnson, and it appears that his opinions were expressed eleven years before issuance of the report. In the interval, says the report, "All the optical examinations have been made of equal standard, and the standard has been appreciably raised."

The British optical societies, through their periodical examinations, are evidently making a sincere attempt to raise the standard of the refracting optician. If the sweeping governmental plan for socialized medicine is enacted into law, it seems possible that the services of British refracting opticians will be enlisted upon the basis of an important degree of professional recognition, in spite of the contention of many British ophthalmic surgeons that the optical practitioner should be utilized only under direct medical supervision.

The report of the "ad hoc" Committee of the British Opticians urges, as has been so often urged, and as is argued by

the optometrists of the United States, that the numerical strength of ophthalmic surgeons is entirely inadequate to provide for the needs of the general public. The "ad hoc" report quotes the records of the British Medical Association as showing that there are only "1,000 ophthalmic surgeons and ophthalmic medical practitioners to deal with the requirements of 45,000,000 people, including surgical and pathological work." The number of British optical practitioners is given as in the neighborhood of 7,000.

The report of the Committee devotes a good deal of space to the history of refraction, with a view to showing "that ophthalmic optics has developed as a distinct and individual field of work." Arguments along these lines, which have been indulged in by both the medical and the optical protagonists in the general controversy, are beside the mark and are certainly not of vital significance. In the days in which physicians advised their patients to choose lenses in any optician's shop, it is quite certain that the said opticians did nothing more scientific than to grind or sell lenses. On the other hand, the outstanding pioneer in the refractive development of the past 85 years was a Dutch physician, F. C. Donders, who conducted his exhaustive investigations within the eye department of a university medical clinic.

The vital question now is how best to serve the public interest. The ultimate effect of the controversy between optician and physician, so far as controversy really exists, is likely to be a steady improvement of the standards of refraction work performed by both groups. Optometry propaganda in the United States has been an added stimulus in the movement for better standards among ophthalmic surgeons. In this country, in spite of the fact that there is much room for improvement, the standard of refraction work among ophthalmic surgeons is far ahead

of the standard among refracting opticians or optometrists, although a few states have done much to elevate the level of optometric practice within their borders.

There is some logic in the argument that physicians should not refract without a certificate of proficiency in this activity. But there is a very much greater need for restricting the optometric license, throughout the country, to those whose general and professional standards of education make it safe to entrust them with such responsibilities. It is rather probable that the centralized British system will show more rapid improvement, and greater justification for public confidence in the certified refracting optician, than the activities of optometric boards of examiners throughout the United States.

Another weakness of the report issued in behalf of the British opticians lies in its emphasis upon the fact that much of the time of the ophthalmic surgeon is devoted to general surgical and medical care of his patients, as distinct from the measurement of refraction. The report appears to overlook entirely the other fact that the optician is usually a merchant who devotes a great proportion of his time to purely commercial and mechanical phases of his business.

Sooner or later the general public will act as umpire in the tug-of-war between ophthalmologist and refracting optician, as it did a hundred years or so ago in the battle for the establishment of a dental profession divorced from the practice of medicine so far as licensure was concerned. Apart from questions of science and philanthropy, the two professional groups have an economic stake in the outcome; and the public, ignorantly or wisely, will in turn also decide upon the basis of self-interest.

Cost of service will receive due consideration, but, in the end, quality of

service will be the deciding factor. Improvement in professional standards, in either camp, will not in the long run lower but raise the cost of service so far as individual refractive prescriptions are concerned, and yet may ultimately lower the cost of service by reducing the frequency with which customers or patients are reexamined or pass from one examiner to another. Those who fear the results of competition should recognize that improvement in any line of service to the public usually broadens recognition of need and therefore increases demand for such service. Economic pressure may force a considerable section of the public to seek for a while the apparently cheaper type of service; but, on the average, those who are able to pay for better and more expensive service will usually be willing or eager to do so. W. H. Crisp.

REHABILITATION OF THE WAR-BLINDED

American war-blinded soldiers in World War II will not return to their homes without having had the benefit of the best possible training in matters connected with their adjustment to civilian life and their future as civilians. Under the direction of The Surgeon General of the United States Army, a program has been set up at Old Farms Convalescent Hospital (Sp), Avon, Connecticut, which will return the blinded service man to his community, with a knowledge of his own abilities and with a desire to resume his normal place in his own community life.

New methods of training the blind are being developed at Old Farms—methods which are designed to fit the individual trainee, and designed for the veteran—using as a basic principle the necessity of seeing to it that the blinded veteran regains completely his own self-confidence. The program aims at showing the man

that, though blinded, he need make very little change in his plans for the future.

The soldiers blinded in this war are for the most part young men and, as young men, they of course have all of the ambitions, dreams, and plans that American young men have. Their blindness has come to them with a terrible suddenness. There has been no time for them to sit down to think or plan prior to its arrival. The result is that when the soldier is told that he is blind, he at first sees toppling about him all of his future and feels that he is doomed to a life of dependency and helplessness. The Old Farms program in conjunction with programs at Valley Forge and Dibble General Hospitals, which treat the men surgically and medically, has done much to remove this feeling and the soldier goes back to his civilian life with an ambition to get to work and to carry on with his business of living.

Old Farms is under the command of Col. Frederic H. Thorne (MC), one of the Army's outstanding ophthalmologists, and is staffed by Army officers, enlisted personnel, and civilian instructors who are trained not only to work with the blind, but to work with blinded soldiers. The program covers a period of 18 weeks, which is felt to be the minimum time in which the best possible job can be done in social adjustment and the maximum time it is possible to hold most of these men in such a program without taking the risk of institutionalizing them in their outlook. All Army blinded will go to Old Farms prior to discharge. The program is four-fold. In the first place it involves general orientation, and in this orientation emphasis is placed on adapting methods to the man, not the man to preconceived methods. One of the basic things done is to train these soldiers to go about the grounds of the Hospital without canes and without aids of any

kind. In the accomplishment of this purpose lies a great deal of the self-confidence which Old Farms wants to put into the men. They learn that, in familiar surroundings, they can go where they want to go, when they want to go, and as they want to go, without depending on any one with sight. The result is that many visitors to Old Farms have been startled to find they have been talking to men whom they have met on the grounds who were blind and who they had no idea were blinded. The second part of the training involves attendance at classes. A wide variety of classes, which includes virtually anything that any man might want to know more about, is available. Work with power machinery such as drill presses, lathes, and other machines, agricultural work, industrial-therapy work in which the hobby angle is stressed, music, Braille, and dozens of others make up the approximately 45 courses. The man is encouraged to take as many of them as he will and can, and to develop new interests if former ones seem inadequate to his new status. Throughout, however, while the man has advice and guidance, his final decision as to his future is his own. An important factor of the courses has been a practical phase in which men are sent into Hartford factories and war plants doing the work of sighted men, beside and in competition with sighted men, and making a record in the doing which has considerably startled local industrialists. Their production record is high and their accident record is zero. The third phase of the work covers the all-important—to the American boy—problem of athletics. Gone are the days of setting-up exercises and long walks. Instead, these war veterans find they can, with almost no exception, take part in and enjoy the sports which they enjoyed before they became blinded. A well-rounded athletic program includes

horseback riding, golf, bowling, roller skating, ice skating, winter sports, swimming, gymnasium work, wrestling, boxing, fishing, and many other activities, and the men soon find that they can still enjoy what they did.

The final division of the program is that of recreation, and under the direction of competent Red Cross Field Representatives, an extensive recreational program is provided. The men go to dances, concerts, dinner parties, plays, movies, sports events, and they play cards, checkers, and all the many games they knew before. Here again the man finds that his blindness does not mean that he will spend his life as a drag on any party he may attend. He finds that here again normalcy is possible.

When the man finishes his 18 weeks at Avon he is given a certificate which certifies his readiness to return to civilian life, having fulfilled the standards of social adjustment set up for him by the Army. He returns with a confidence in his own ability to make a success of his life and he returns with a desire to do something more than exist in endless days to come on a pension. However, the real job will be done by the public, for these men returning to their homes in full knowledge of their potential abilities will expect and will deserve the chance to use them, and if communities will accept them as normal and take them into their normal community life and avoid the silly and, to the men, objectional displays of pity and sympathy so common with the blind, these blinded men will make a success of their lives and will make citizens of whom their communities may well be proud. However, the answer will lie, not with the Army, not with the man, but with his community.

When he leaves Avon he leaves with the basic training necessary, and he becomes the active interest of the Veterans

Administration. It is the job of the Veterans Administration to see that the man receives any additional or specialized training he may want; that his rights under the GI Bill of Rights are protected; that he is given assistance in locating a suitable job, and that he is given the aid and counsel which will mean the proper start. Once he leaves Avon, he is a discharged soldier and the Army loses the right to aid him further, but the men at Old Farms have found that the interest of the Army does not end with his discharge, and there is rapidly growing up something which resembles closely the alumni spirit to be found in schools and colleges of this country.

The Army, the blinded soldier, the Veterans Administration, and the public make up a team which, together, can end for all time dependency and helplessness for these men.

BOOK NOTICE

STUDIES OF CIRCULATORY DISTURBANCES, PULSE WAVE VELOCITY AND PRESSURE PULSES IN LARGER ARTERIES IN CASES OF PSEUDOXANTHOMA ELASTICUM AND ANGIOID STREAKS. By Uno Carlborg. Acta Medica Scandinavica, Suppl. CLI. Paper covers, 209 pages with 19 illustrations. Uppsala, Appelbergs Boktryckeri A.-B. 1944.

As the title suggests, this monograph is not primarily an ophthalmologic treatise. This excellent piece of clinical investigation does, however, have ophthalmologic interest, just as it has interest for the dermatologist, internist, and vascular physiologist. The author seems to

have integrated well the contributions of each of these fields in the present study. The first of the two parts of the paper is devoted to the clinical aspects of the problem. There is an extensive historical review which includes most of the 130 known cases of associated pseudoxanthoma elasticum and angioid streaks. The author uses the name "Grönblad-Strandberg's syndrome" for the ophthalmologist and dermatologist, respectively, who elucidated this association. He presents a careful picture of the skin and eye findings. In both organs, the pathologic processes consist in degenerative changes in elastic connective tissue.

Fifteen typical patients are presented, in detail, and the author was able to demonstrate that symptoms of peripheral circulatory insufficiency were common. Pathologically, the vessels of the extremities, the abdominal viscera, the eye, and the skin showed elastic-tissue degeneration. Cardiac and aortic findings, on the other hand, were not marked, and the author points out that in these structures elastic tissue is relatively sparse.

The etiology of the disease is unknown, except for the facts that it is a dystrophy of the elastic tissue throughout the body, and that it is hereditary, being transmitted as a recessive. Blood chemistry, metabolic, and other laboratory studies show no characteristic abnormalities, nor are the circulatory symptoms pathognomonic. Hemodynamic studies undertaken by the author did, however, show characteristic features. The second part of the monograph deals with these observations. Carlborg was able to demonstrate decreased pulse-wave velocity. Sphygmograms showed characteristic abnormalities, and oscillometric studies showed abnormally

low curves. Comparisons with normal individuals and with senile arteriosclerotics revealed the changes to be, on the whole, peculiar to the group of patients under investigation. The author holds that the same explanations advanced for the altered physiology of the circulation in arteriosclerotics cannot be applied to these patients; since they are too young in most instances, and since the author was unable to find any reasons to suppose that there was actual narrowing of the caliber of the vessels. He concludes that the altered hemodynamics in patients with the Grönblad-Strandberg syndrome are the result of the elastic degeneration in the muscular vessels. This atrophy permits the damping, "shock-absorber" effect of the vessel musculature (hysteresis) to play a dominant role in pulse-wave transmission, and explains to a great extent the decrease in pulse-wave velocity and the other abnormal circulatory findings.

The author feels that this study contributes in a measure to the knowledge of the physiology of the circulation, since this disease enables one to study the manner in which the vessels function, *in vivo*, in the absence of the elastic component. He feels that too little emphasis has been placed, hitherto, on the role of smooth-muscle hysteresis.

The monograph represents clinical investigation on its highest plane, characterized by painstaking care in each detail. It may well be considered a model for good clinical research, and should constitute interesting reading for a student of any of the medical specialties from which the author has drawn his material.

Benjamin Milder,

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. General methods of diagnosis
2. Therapeutics and operations
3. Physiologic optics, refraction, and color vision
4. Ocular movements
5. Conjunctiva
6. Cornea and sclera
7. Uveal tract, sympathetic disease, and aqueous humor
8. Glaucoma and ocular tension
9. Crystalline lens
10. Retina and vitreous
11. Optic nerve and toxic amblyopias
12. Visual tracts and centers
13. Eyeball and orbit
14. Eyelids and lacrimal apparatus
15. Tumors
16. Injuries
17. Systemic diseases and parasites
18. Hygiene, sociology, education, and history
19. Anatomy, embryology, and comparative ophthalmology

6

CORNEA AND SCLERA

Friedenwald, J. S., and Buschke, W. Mitotic and wound-healing activities of the corneal epithelium. *Arch. of Ophth.*, 1944, v. 32, Nov., pp. 410-413; also *Trans. Amer. Ophth. Soc.*, 1944, v. 42.

This investigation was undertaken in an effort to discover the physiologic controls and biochemical aspects of mitotic and wound-healing activities. The method of assay of mitosis depends upon routine counts of a meridional strip of rat cornea. In normal young adult rats there are approximately 5,000 to 6,000 mitoses per cornea, or 100 mitoses per strip counted. Normal variations range from 50 to 200 mitoses per strip. However, mitotic activity cannot be gauged solely by the number of mitoses present at a single moment, since that number is affected both by the rate at which cells enter mitosis and by the rate at which cells pass through the mitotic cycle.

Other investigators have shown in other organs that colchicine arrests the

mitotic cycle in metaphase but does not influence the rate at which cells enter mitosis. Hence, the number of cells observed in mitosis at a fixed time after administration of colchicine furnishes a measure of the rate at which the cells enter mitosis. By a combination of methods it was found that the duration of mitosis in the normal cornea was about seventy minutes and the intermitotic interval for the basal cells approximately one week. Under suitable conditions the mitotic rate could be maintained almost at the normal level in the enucleated eye kept in a moist chamber in the incubator.

Histamine, acetylcholine, physostigmine, pilocarpine, carbaminoylcholine chloride, and atropine were found to be without effect on the mitotic activity. Epinephrine, on the other hand, produced a notable inhibition of the entrance of cells into mitosis, without disturbing the development of the mitosis once it had begun. By intramuscular injection of epinephrine in peanut oil, mitosis in the cornea could be suppressed for many hours. Ephedrine had a similar effect.

The number of cells observed in mitosis after superior cervical sympathectomy was normal in simple counts but was greatly reduced after administration of colchicine. Cocaine, ether, and barbiturates produced notable inhibition of the initiation of mitosis. Mechanical damage to less than 0.1 percent of the epithelial cells of the cornea caused inhibition of mitosis in the remaining, apparently uninjured, cells for several hours.

Ultraviolet light and radiation with beta rays of radium also inhibited the onset of mitosis. Decrease in temperature to 30° C. did not make it impossible for cells already in mitosis to complete their division. Deficiency in vitamin A decreased the rate of mitosis and, to a somewhat lesser degree, the progress through the mitotic cycle. Up to the present the authors have encountered no agent which produces an increase in the rate of mitosis though with many substances there is an overshooting of the normal rate of mitosis for a brief period after recovery from inhibition.

The second part of the paper deals with wound healing. In order to separate the primary phenomenon of wound-healing from the inflammatory reaction and secondary infection of large wounds, the authors chose for study minute epithelial defects produced by needle pricks of the corneal surface. One hour later there was no visible change. Two hours after the injury the basal marginal cells had changed their orientation and lay with their long axes radial to the hole. Three hours after the injury the majority of the holes were covered. After the initial period of lag of one hour, the rate of cell movement in closing these small holes was 0.25 microns per

minute. The wound-healing phenomenon proceeded equally well in enucleated eyes kept either in a moist chamber or in aerated solutions in the incubator.

Wound-healing in the corneal epithelium occurred at a pH of from 4.5 to 9.5. The process was much less sensitive to pharmacologic interference than was mitosis. Local anesthetics such as cocaine and tetracaine inhibited the process, but of the general anesthetics administered systemically only morphine had a measurable effect. Ultraviolet radiation did not inhibit wound healing except in doses producing sloughing of the epithelium. Anoxia, sodium cyanide, and sodium azide inhibited the healing process. Tables are given which report on many other changes than those mentioned. (References.) R. W. Danielson.

Mann, Ida. Ariboflavinosis. *Amer. Jour. Ophth.*, 1945, v. 28, March, pp. 243-247. (3 color plates, references.)

Pannabecker, C. L. Keratitis neuroparalytica. Corneal lesions following operations for trigeminal neuralgia. *Arch. of Ophth.*, 1944, v. 32, Dec., pp. 456-461; also *Trans. Sec. on Ophth.*, *Amer. Med. Assoc.*, 1944, 94th mtg.

This is an analysis of the corneal lesions complicating 878 operations for trigeminal neuralgia. Corneal anesthesia and lagophthalmos are the important factors in the production of corneal lesions. Neuroparalytic keratitis may be classified as follows: (1) parenchymatous, with absence of ulceration; (2) superficial, a benign form, with areas of desquamation; (3) ulcerative, with a tendency to regression and moderate corneal damage; and (4) persistent. Exposure keratitis is a degenerative condition due to desiccation result-

ing from lagophthalmos. Lagophthalmos may develop as the result of surgical trauma of the facial nerve. Corneal anesthesia and lagophthalmos combined give the greatest incidence of corneal lesions (65 percent). Operations complicated by the presence of neoplasms are more likely to result in paralysis of the facial nerve and exposure keratitis. The patient with corneal anesthesia following operation for trigeminal neuralgia is most susceptible to development of neuroparalytic keratitis during the first few months after operation, but the disturbance may occur much later. Early tarsorrhaphy should be performed in doubtful or suspected cases and the lid be thus partially closed for six months. (4 tables, references.)

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Nuri Fehmi Ayberk. Adie's syndrome. Göz Klinigi, 1944, v. 1, no. 6, p. 227.

After quoting some literature the author gives the differential points between Adie's syndrome and the Argyll-Robertson pupil.

Joseph Igersheimer.

Pendse, G. S. Allergy in tubercular affections of the eye. Indian Jour. Ophth., 1944, v. 5, Oct., pp. 63-66.

A general discussion of ocular tuberculosis and tuberculin treatment is followed by report of two cases in which uveitis was thought to be due to tuberculous allergy and recovered after local and general treatment, the latter including injection of tuberculin.

W. H. Crisp.

Rahim, S. A. A case of polycoria. Indian Jour. Ophth., 1944, v. 5, Oct., p. 67.

A boy aged 12 years presented the conditions shown in illustrations of the two eyes. In the right eye, with very poor vision, only a small amount of iris was present, in the form of a K-shaped figure probably connected at several points with the ciliary body. The optic disc was deeply cupped, the cornea slightly larger than that of the left eye, and the tension 30 mm. (instrument not mentioned). The left eye, with vision of 6/24, showed a spindle-shaped pupil at the lower inner quadrant next to the limbus, a smaller irregular pupil at the lower outer quadrant, and five holes in the iris tissue which occupied a little more than the upper half of the pupillary area and was connected by a bridge with the ciliary body below. The fundus could not be properly seen, and the tension is given as 40 mm. W. H. Crisp.

Scobee, R. G. Rubeosis iridis diabetica. Texas State Jour. Med., 1944, v. 40, Dec., p. 432.

A case of rubeosis iridis diabetica is reported, with successful surgical result in the secondary glaucoma associated with the rubeosis. Cyclodiathermy was the procedure used. The possible etiology of rubeosis of the iris is discussed, and also possible reasons for the success of the cyclodiathermy.

Theodore M. Shapira.

Sverdlick, José. Phenomena of secretory activities in the epithelium of the ciliary processes. Reprint from Arch. de Histologia Normal y Patologica (Buenos Aires), 1944, v. 2, July, pp. 248-265.

The experimental material was de-

rived from man and from the dog and rabbit. It was possible to demonstrate in the cells corresponding to the superficial layer of the ciliary processes a granular substance, the character of which differs from the mitochondria and from the lipid vesicles described by various authors, but possesses characteristics corresponding to secretory granules. By the location of the granules in the part of the cell bathed in aqueous humor, it is deduced that the cells are related to the process of formation of this fluid. (8 figures, references.)

GLAUCOMA AND OCULAR TENSION

Gözcü, N. I. Pathogenesis and treatment of the glaucoma syndrome, and results of peripheral iridectomy. *Göz Klinigi*, 1944, v. 2, no. 1, p. 1.

The author believes like Magitot that glaucoma is mainly due to disturbance of the uveal circulation, the cause of which is a sympathicotonia in the eye. He thinks sympathetic ganglia in the eye are destroyed by peripheral iridectomy, with the result that the local sympathicotonia is cured. Three successful peripheral iridectomies in glaucoma are discussed.

Joseph Igersheimer.

Kronfeld, P. C. Gonioscopic correlates of responsiveness to miotics. *Arch. of Ophth.*, 1944, v. 32, Dec., pp. 447-455; also *Trans. Sec. on Ophth.*, Amer. Med. Assoc., 1944, 94th mtg.

Angle-block glaucoma, wide-angle glaucoma, glaucoma secondary to iridocyclitis, glaucoma after cataract operation, and glaucoma associated with capsular exfoliation are discussed in some detail, with particular refer-

ence to gonioscopic findings as correlated with responsiveness to miotics. In angle-block glaucoma it is probable that miotics favorably affect the glaucoma largely through their miotic action. Gonioscopic studies have shown that in this type the smallest sector of open angle that is compatible with normal intraocular pressure is 70 to 90 degrees of arc.

Glaucoma caused by peripheral anterior synechias resulting from delayed restoration of the anterior chamber after cataract operation is discussed. Three variations of the anterior edge of the adhesions are found; namely a solid, sharply demarcated line; a fuzzy, scalloped zone, and multiple thready, filamentous adhesions. The first type gives rise to the more serious cases of glaucoma. Most cases of glaucoma following cataract extraction respond in some degree to miotics. In eyes with senile capsular exfoliation, irrespective of whether or not glaucoma is present, the gonioscope shows particles of exfoliated capsular material deposited on both walls and in the vertex of the angle, in addition to pronounced pigment infiltration of the trabecula. In cases of so-called primary glaucoma not of the iris-block type and of glaucoma secondary to iridocyclitis, there is no apparent relation between the gonioscopic picture and the efficacy of miotics.

CRYSTALLINE LENS

Hughes, W. L., Guy, L. P., and Ro-main, H. H. Use of absorbable sutures in cataract surgery. *Arch. of Ophth.*, 1944, v. 32, Nov., pp. 362-367.

After trying the different kinds of absorbable and nonabsorbable sutures,

the authors come to the conclusion that absorbable suture material for use in cataract operations is more desirable than a material that must be removed, since complications incident to removal of the sutures are avoided. The nearest approach to the ideal suture, holding seven to ten days, colored for ease in identification, economical in price, easy to handle, and well tolerated by tissues is 00000 plain surgical gut. But this suture is less flexible than silk, and the authors do not feel that it fulfills all the requirements for an ideal suture. (3 figures.) R. W. Danielson.

Samuels, Bernard. Complicated cataract associated with spontaneous detachment of the retina. *Arch. of Ophth.*, 1944, v. 32, Nov., pp. 416-422; also *Trans. Amer. Ophth. Soc.*, 1944, v. 42.

In three recent papers the author has discussed and illustrated the pathologic changes in the lens in perforating ulcer of the cornea, in leucoma adherens, and in spontaneous iritis, respectively. The purpose of the present studies has been to ascertain the changes which may occur in a lens as a result of various pathologic conditions in the globe. The cataract that is associated with retinal detachment often has a peculiar yellowish-white hue.

The material consisted of microscopic preparations of lenses from 21 globes. There were 11 specimens which were associated with a history or anatomic signs of myopia. Only cases of spontaneous detachment were chosen, those being excluded in which the condition was caused by tumor, exudative retinitis, angiomatosis of the retina, or by retinitis interna and externa. A majority of the 21 globes were removed because of development of the well-

known triad that may follow sooner or later in the wake of the detached retina; namely, iritis, secondary glaucoma, and cataract. A globe with an old detachment or one with a potential detachment is intolerant to ever so slight a blow.

In all probability, in many cases iritis should not be considered a complication of the retinal detachment but should rather be regarded as a sequel of a hidden inflammatory process that antedated the detachment and was in fact the original cause of it. Occasionally a detachment causes a complicated cataract without any sign of inflammation either clinical or pathologic in the anterior part of the globe. Causes other than the detachment that were believed to have contributed to development of the cataract were iritis, altered metabolism, and glaucoma.

The cause of inflammation of the iris associated with retinal detachment has never been clearly explained. However, that the iritis is produced by toxins in the stagnant subretinal fluid seems to be proved by the fact that after puncturing the sclera and allowing the fluid to escape, as advocated by Meller of Vienna, the iritis more often than not quiets down. A factor in altered metabolism considered to have exerted an unfavorable influence on the lens was interference with the outflow of intraocular fluid into the papilla. Then, too, a disturbance of the general metabolism of the body may set up inflammation in a diseased globe whereas it may have no effect on a sound eye.

The author discusses associated changes in the retina, subretinal fluid, choroid, vitreous, ciliary body, and iris. There was no evidence that the choroid was the source of the subretinal fluid, particularly since the pigment epi-

thelium was never raised. Specimens from 17 globes permitted examination of the vitreous anterior to the retina. In five cases the vitreous was detached and in five others it was traversed by membranes. In three cases it contained blood. A "step" in the retina at the point of a detachment of the vitreous is an anatomic sign of traction. This observation seems to substantiate the theory that most retinal detachments result from traction by bands of broken-down vitreous. The iris was often severely irritated, the ciliary body seldom. Clinically, iris bombé in a globe that is known to have been blind for a long time may well be regarded as a sign of retinal detachment.

Exhaustive microscopic studies of the lenses were made. When this series of lenses was compared with the three previous series as to the extent of the changes and their frequency and distribution, the following characteristics of cataract associated with spontaneous retinal detachment were apparent: (1) the presence of well-defined vesicular cells in the posterior quadrant of the lens: these cells were observed to occur in far greater abundance and frequency than in the other series; (2) the lining of the entire capsule by a single layer of epithelial cells in greater abundance than previously noted.

The author concludes that the presence of epithelial cells in the posterior quadrant of the lens, where normally there are no cells, implies that they had proliferated in that direction in response either to a chemical agent or to an inherent impulse to grow backward. (8 figures, references.)

Thomas, C. I. Suction instrument for cataract extraction. Amer. Jour.

Ophth., 1945, v. 28, March, p. 317. (One figure.)

Verhoeff, F. H. Removal of the ruptured capsule in operations for cataract. Arch. of Ophth., 1944, v. 32, Nov., pp. 407-409; also Trans. Amer. Ophth. Soc., 1944, v. 42.

In the so-called intracapsular operation for cataract, the capsule sometimes ruptures. If the broken capsule recedes into the eye, the extraction usually becomes extracapsular. When rupture does occur, it is due to one or more of the following causes: (1) Imperfect technique: the incision is too small for the cataract, or, more often, the operator through impatience exerts too great traction with the forceps or too little pressure with the expressor. (2) The forceps is poorly adjusted and tends to bite a hole in the capsule. (3) The patient is a "bad actor," making a wide movement of the eye at a critical time.

There are two types of rupture of the capsule that are really fortunate occurrences, for each not only insures complete removal of the capsule but as concerns loss of vitreous makes the operation safer than when the cataract is removed without rupture of the capsule. In the first of these types, the capsule ruptures below and is completely removed by the forceps, the cataract being left within the eye. The nucleus should then be expressed with great care, and the sutures should be pulled up before the remaining lens material is irrigated out. In the second type, the capsule ruptures elsewhere but remains prolapsed in the wound after the nucleus has been expressed. Such a capsule can easily be picked up with forceps and completely removed.

The author has devised a simple pro-

cedure to apply to this situation. The procedure consists essentially in keeping the anterior chamber filled while the capsule is grasped and removed with the angular capsule forceps. After one suture has been tied the opening of the wound is so much reduced in size that the chamber can easily be kept sufficiently distended by gentle, continuous irrigation with isotonic solution of sodium chloride. For the irrigation a small metal tip attached to a rubber bulb is used. Occasionally the author has carried out the irrigation with his right hand while he removed the capsule with a forceps held in his left. He prefers, however, that a capable assistant carry out the irrigation so he can give his entire attention to removing the capsule. (References.) R. W. Danielson.

RETINA AND VITREOUS

Agatston, S. A. Relation of blood dyscrasia to retinopathy. *Arch. of Ophth.*, 1944, v. 32, Nov., pp. 388-390.

All types of retinopathy are based on localized structural changes in the blood vessels and capillaries, irrespective of the cause. Since nutrition of the walls of small vessels and capillaries depends on the quality as well as the quantity of the blood within, qualitative or quantitative reduction results in degenerative changes.

The following blood dyscrasias may be responsible for ophthalmic manifestations: chlorosis, pernicious anemia and sprue, Jaksch anemia (anemia infantum pseudoleukemica), secondary anemia, sickle-cell anemia, aplastic anemia, hyperplastic anemia, erythremia (polycythemia vera), secondary polycythemia, purpura hemorrhagica,

hemophilia, scurvy, lipemia, leukemia, sepsis, and diabetes. The author gives briefly the fundus picture of each of these diseases. (References.)

Ballantyne, A. J. Observations on the pathology of thrombosis of the central vein of the retina. *Trans. Ophth. Soc. United Kingdom*, 1943, v. 63, pp. 137-142.

The author presents the pathologic findings in the case of circinate retinopathy reported by Loewenstein and Garrow (see below). The central vein was traced with difficulty as it was obliterated by an organized thrombus or by sclerosis, but there were open venous channels situated more peripherally in the nerve. Forward the central vein came into view as a single vessel, or as two, three, or four channels formed either by canalization of an old thrombus or by formation of new venous channels. The case seems to prove that it is possible to have thrombosis of the central vein without hemorrhage. Two changes were taking place: gradual localized occlusion of the vein and equally gradual formation of collateral channels. (7 illustrations.)

Beulah Cushman.

Ballantyne, A. J., and Loewenstein, A. The pathology of diabetic retinopathy. *Trans. Ophth. Soc. United Kingdom*, 1943, v. 63, pp. 95-115.

This histologic report is based on examination of nine specimens, the posterior half of the eyeball being used in eight and the whole eyeball in one. The endothelial cells were found sprinkled with fatty droplets of varying size and density, sometimes arranged as a belt around the lumen. In other places, where the fatty infiltration of the endo-

thelium was of notable degree, the wall of the vessel had become ectatic, forming an aneurysm. Clinically the aneurysmal changes appeared as globular bodies attached to the vessels in series, like strings of beads, or as isolated spherical bodies consisting of closely packed red blood corpuscles enclosed within a capsule. If unconnected with a vessel these bodies are called encysted hemorrhages. They were identified as the small round spots found around the macula and described clinically as punctate hemorrhages.

Groups of fatty droplets were found 7 to 10 microns under the retinal surface and 40 to 50 microns deeper were found larger droplets. In the advanced cases retinal degeneration was extensive, with preretinal vessels embedded in a deep layer of primitive connective tissue which covered the surface of the retina, and which the authors call retinal pannus. Phlebosclerosis was seen in two forms: a nonsymmetrical fibrillary thickening of the vein wall with normal lumen, and a great thickening with complete hyalinization and narrowing of the lumen. (15 illustrations, references.) Beulah Cushman.

Knapp, Arnold. **Spontaneous retinal reattachment.** *Arch. of Ophth.*, 1944, v. 32, Nov., pp. 403-406; also *Trans. Amer. Ophth. Soc.*, 1944, v. 42.

The course of serous retinal detachment is sometimes curiously modified when the detachment of the retina remains stationary and there is reattachment which gives rise to a characteristic ophthalmoscopic picture. The detachment is shallow, and its upper boundary is bound down by chorio-retinal changes, which constitute the most striking sign. The reattached, flat retina is generally changed to a

paler, yellow gray; there are characteristic branching white subretinal lines and areas where the choroidal markings are more distinct and irregular retinal pigmentation is present. The upper boundary consists of organized exudate, which extends across the fundus below the disc in a curved or in a more or less straight line to the periphery on each side and divides the fundus into two dissimilar parts.

The present accepted explanation of the cause of retinal detachment assumes the presence of degenerative changes in the retina and in the vitreous body, with the formation of an adhesion between these two structures, this adhesion resulting in a tear of the retina due to rotatory movements of the vitreous body. This does not explain the causation of the detachment in the cases observed and described by the author. In these 16 cases the detachments occurred in young people, in whom degenerative changes are not frequent. Also, in the case of a dialysis the cause is entirely physical. Moreover, the adhesion of the vitreous to the underlying retina in the periphery of the eyeground is normally unusually strong, so that a pathologic process which binds the vitreous and the retina together need not be present. It is possible that the firmer texture of the vitreous body at its base explains why escape of the vitreous fluid in this type of detachment is moderate. Finally, an important factor in the shallowness of a detachment limited to the lower half of the eyeground may be the weight of the vitreous body, which acts most on the lower half of the fundus.

Notwithstanding the prospect of self-limitation of a retinal detachment which is limited to the lower half of the fundus, the author advises early

operation to avoid involvement of the macula and to preserve the visual field. (References, 2 drawings.)

Loewenstein, A., and Garrow, A. A contribution to the anatomy of circinate retinopathy. *Trans. Ophth. Soc. United Kingdom*, 1943, v. 63, pp. 120-135.

The authors give the histopathology of circinate retinopathy in the fifth case to be described since Jonathan Hutchison first mentioned the condition in 1876. E. Fuchs described it in 1893.

The eye was fixed in formol, sectioned in front of the equator, and studied at the slitlamp after removal of the vitreous body. The piece of retina containing the circinate changes was excised, cleared in glycerin, and examined microscopically, unstained and in bulk. The nerve-fiber pattern was clearly visible except in the circinate area. The discrete white shining dots sheathed vessels in several places, and with higher power the spots were resolved into rows of discrete reflecting droplets of different size, surrounding the clearly visible thickened vessel walls.

The piece of retina was then washed out and stained in bulk. With scarlet red the arcuate area appeared shining red. The higher power revealed that the sheathing of the larger vessel consisted of fat. Parts of the circinate area were embedded in gelatin, sectioned vertically, and counterstained with a thin solution of hematoxylin. The con-

trast of the nuclei with the red fatty droplets was very impressive. Two absolutely different foreign substances were found: fatty droplets mostly in round red patches situated throughout the whole retinal thickness, and a non-fatty substance in large spaces corresponding to the internuclear layer.

The vascular changes were at different levels. The capillaries varied from 3 to 15 microns in width and were dilated locally to form aneurysmal ectasias with different degrees of fatty-wall change. In some walls there was leakage, with exit of red blood corpuscles. Perfect chains of aneurysms emphasized the degree of vascular damage. Fatty changes were present in the central part of the intraretinal hemorrhages, and new blood vessels were seen. Most of the endothelial cells contained one or more fatty droplets. Apparently empty spaces in the outer granular layer corresponded to exudates. A gelatinous tissue covered the greater part of the retinal surface, and contained red blood cells and some vessels. The choroidal vessels were found to be normal. Their stroma contained fatty droplets.

The causal genesis may differ in different cases, and the authors conclude that circinate retinopathy is not an etiologic clinical entity but a form of cellular reaction in the retina. (15 illustrations, references.)

tachment. *Indian Jour. Ophth.*, 1944, v. 5, July, pp. 55-59.

A general discussion of the subject, with reproductions of some illustrations from Arruga and from Cole Marshall.

Sverdllick, J. Influence of the hypophysis and the suprarenal gland upon retinal pigment in "*Bufo arenarum*" Hensel. Reprint of paper presented to Sociedad Argentina de Biología, June 11, 1942. (See Section 19, Anatomy, embryology, and comparative ophthalmology.)

Wolff, Eugene. Ghost-rings on the internal limiting membrane of the retina. *Trans. Ophth. Soc. United Kingdom*, 1943, v. 63, pp. 116-119.

The author identifies the rings often seen on the internal limiting membrane of the retina in histopathology as the product of disintegrated mononuclear cells. He feels that they represent one stage in disappearance from the vitreous cavity of those mononuclear cells derived from the ciliary body or retina. Probably the cell becomes swollen and the nucleus passes through the cell membrane leaving a ghost-ring, while later the nuclear contents pass out of the nuclear membrane leaving the smaller ghost-ring and finally the rings break down into granules. (4 illustrations.)

OPTIC NERVE AND TOXIC AMBLYOPIAS

Basar, Irfan. Optic atrophy after intestinal hemorrhage. *Göz Klinigi*, 1944, v. 2, no. 1, p. 7.

A 39-year-old patient suffered from duodenal ulcers for twelve years. After hematemesis lasting several days he

lost the vision of his left eye. Some weeks later this eye showed atrophic disc, constriction of the visual field, and central scotoma. The patient could count fingers at 3 feet.

Joseph Igersheimer.

Cohen, Martin. Binocular papilledema in a case of torulosis associated with Hodgkin's disease. *Arch. of Ophth.*, 1944, v. 32, Dec., pp. 477-479.

Torula, a pathogenic yeastlike organism, may cause disturbances in the central nervous system, often with fundus lesions. It is noteworthy that in at least 10 percent of the reported cases the torulosis was associated with Hodgkin's disease. This is too frequent an occurrence to be a mere coincidence, but so far the relationship of the two diseases has not been established.

The author reports the case of a 36-year-old woman who was first seen because of visual deterioration of two months standing. She complained of severe headaches, accompanied by drowsiness and intermittent vomiting. The cervical lymph glands were enlarged. Both fundi showed papilledema, hemorrhages and exudates. The cerebrospinal fluid pressure was greatly increased, and torula histolytica could be cultured from the fluid. This organism was also found in cultures of the urine. Administration of sulfadiazine had no marked effect. Ventricular drainage was done for a week with some visual improvement. The patient developed a superimposed intracranial infection with nonhemolytic streptococci. The discs remained edematous and became grayish, the vision being completely lost. The patient's condition grew progressively more serious, with nuchal rigidity, opisthotonos and tremors of the upper extremities. He

died in coma. At autopsy, findings typical of Hodgkin's disease were found in the thoracic, abdominal, and cervical nodes. Torulas were demonstrated in the brain tissue, as well as in the secretions covering the cortex of the cerebrum and pons. Pericellular infiltration of the pia-arachnoid of the optic nerve was observed. (One color plate, including 5 figures; references.)

John C. Long.

Cox, R. A. Amblyopia resulting from hemorrhage. *Arch. of Ophth.*, 1944, v. 32, Nov., pp. 368-371.

Occasionally after profuse distant hemorrhage there is noticed immediately, or more frequently after the lapse of days, a sudden diminution of vision, which often goes on to complete and permanent blindness, with the ophthalmoscopic picture of atrophy of the optic nerves. Deprivation of blood supply to any tissue will, if sufficiently prolonged, cause impairment or loss of function. If there is any correlation between delicacy of structure and of function, one may expect that those structures which are concerned with the most delicate functions will be earlier and more readily affected. Thus the retina will suffer before more coarsely constituted organs.

The resulting blindness is usually bilateral, and may be permanent or transitory. It usually comes on between the third and the seventh day after bleeding but may be delayed for some time. Recovery is possible even after light perception has been abolished for several days, provided the pupillary reaction to light is retained. In patients with a more favorable prognosis the amblyopia lasts from a few minutes to many hours. (One case report, fields, references.)

R. W. Danielson.

Flecker, H. Sudden blindness after eating "finger cherries" (*Rhodomyrtus macrocarpa*). *Med. Jour. Australia*, 1944, v. 2, Aug. 19, p. 183.

As early as 1894 reports indicated that eating of the fruit of *Rhodomyrtus macrocarpa* or finger cherry, a plant indigenous to north Queensland, could cause sudden and usually permanent blindness. Since not all who have eaten the fruit have been so afflicted the cases were reviewed as to ripeness of the fruit at the time of eating, and as to the possibility that a fungus, *Gloco-sporium periculosum*, which commonly infests the overripe fruit, might be the causative agent. Seven cases in humans are briefly described, and cases in which blindness ensued in heifer calves and a goat after browsing on the fruit and foliage are recorded. Little is known about the clinical picture in the early stages. The late picture is usually one of primary optic atrophy with sluggish or inactive pupils. Some patients have retained light perception and hand movements in one or both eyes. In 1915 the Department of Education prepared a bulletin for distribution to the local schools of North Queensland, giving pictures of the plant and fruit with a discussion of its dangers. No cases have been reported during the subsequent years. The toxic factor has never been positively identified.

VISUAL TRACTS AND CENTERS

Figueiredo, N. P. de. Ocular symptoms of hysteria. *Rev. Brasileira de Oft.*, 1944, v. 3, Dec., pp. 74-93.

Imaginary blindness appeared due to emotional disturbance. The treatment consisted of an alleged operation, which was repeated several times.

Without anesthesia, on each occasion the eyeballs were grasped with forceps and moved in several directions. A weak solution of zinc sulphate was instilled and the eyes bandaged. The vision steadily improved, to reach normal in about a week. The author devotes a further 15 pages to a review of various ocular symptoms arising from hysteria. (References.) W. H. Crisp.

Oberndorf, C. P. Ocular symptoms of psychogenic origin. *Arch. of Ophth.*, 1944, v. 32, Dec., pp. 443-446.

A mechanism known to the psychiatrist as "displacement" consists in the moving of genital "affects" from a primary object or function to a secondary one. When displaced associations become attached with sufficient tenacity to the secondary object, the latter may assume the functions of the first and may eventually become a welcome substitute for the primary one in fulfilling certain emotional needs of the organism. Substitutions springing from the unconscious as a result of persistent and constant repression of unacceptable "instinctual" urges often come to light. These urges, particularly the sexual ones, may continue when relief and satisfaction are normal. When they are suppressed but not relinquished, the denial of expression gives rise to complaints referred to various bodily systems. Such substitutions may take the form of physical complaints ascribed to many different organs. The ocular complaint may be "eyestrain," pain, blurring of vision, or even blindness.

The relationship of the eye to various neuroses is shown and clinical examples are given. Practical applications of the treatment of ocular neuroses are discussed. Often it is not

advisable to tell the patient at once of the psychogenic nature of his ailment. The clinical psychotherapist must confine himself to presentation of such facts as seen valid in accordance with his method. The soundness of his work rests largely on recognition of the validity of such facts by the patient, and on disappearance of the symptoms when the inhibitions which necessitated conversion phenomena no longer operate.

EYEBALL AND ORBIT

Adler, F. H. The role of exophthalmos in the diagnosis and treatment of Graves's disease. *West Virginia Med. Jour.*, 1944, v. 40, Oct., p. 136.

The earliest sign in the thyrotoxic type of Graves's disease is lid retraction. The cause of lid retraction is unknown. It gives rise to the other lid signs in Graves's disease, such as lid-lag and infrequent winking, and is the cause of the characteristic facial expression of thyrotoxicosis. Lid retraction causes a slight degree of exophthalmos, but simulates a much greater degree. It is not pathognomonic of Graves's disease.

Exophthalmos can be diagnosed only by actual measurement, and even then one can only assert the degree of protrusion of the globe is pathologic when (1) the condition is unilateral and the difference between the two eyes exceeds 1.5 mm. and (2) previous measurements have shown the increase to have occurred when the condition was bilateral. Two types of exophthalmos occur in Graves's disease. One type is due to the same mechanism as causes the lid retraction, hence is of slight degree, occurs in the cases which are thyrotoxic, and disappears when the

lid retraction disappears. No pathology is found in the orbit to account for this type. The other type is due to edema of the orbit, followed by cellular infiltration. It is progressive, especially in hypothyroid individuals, remains or gets worse even though the thyrotoxicosis is cured, and persists after death.

The signs by which this type of ophthalmopathic Graves's disease can be recognized are outlined as follows: (1) edema of the lids, noninflammatory; (2) edema of the bulbar conjunctiva, settling to the lower cul-de-sac, but not involving the palpebral conjunctiva; (3) progressive exophthalmos; (4) early limitation of movement of one or both globes due to proptosis: there is little diplopia since limitations are usually bilateral and in the same direction; (5) exophthalmos out of all proportion to signs of thyrotoxicosis; in fact, strikingly in the inverse proportion; hence most frequently seen in post-thyroidectomy cases. Ten case reports are presented, and the medical treatment outlined.

Theodore M. Shapira.

Gonçalves, Paiva. *Orbital varix (intermittent exophthalmos)*. Rev. Brasileira de Oft., 1944, v. 3, Dec., pp. 57-63.

The patient, a young man, experienced severe pains in the left eyeball upon lowering his head or in ventral decubitus. Upon repeating the necessary maneuver, the eyeball protruded behind distended and congested eyelids. It took one or two minutes for the condition to quiet down, and by this time the pain was of such intensity that if anyone undertook to hold the patient with his head down he made violent efforts to release himself. Enophthalmos was manifest between the crises. The vision was equal to that

of the other eye. The author proposed to try the effect of roentgen rays, and if these proved ineffective to resort to sclerosing injections. (4 photographs.)

W. H. Crisp.

Murphey, P. J., and Schlossberg, L. *Eye replacement by acrylic maxillo-facial prosthesis*. U. S. Naval Med. Bull., 1944, v. 43, Dec., p. 1085.

A detailed description of the method of manufacture of artificial eyes as used by the Naval Dental School at the National Naval Medical center, Bethesda, Maryland, is given. Heretofore much was usually left to be desired in the fitting of prostheses both as to good cosmetic result and as to restoration of normal facial contours. Following study of the usual posterior socket wall and of the functions of the various extraocular muscles it was found that an adequate prosthesis should have a superior fullness to support the upper lid, a posterior concavity to accommodate the rectus muscles, and occasionally an increased inferior lip to prevent ejection of the prosthesis on upward gaze and also to enable the orbicularis to assist in elevation.

Details of the procedure include preliminary study of the patient, including photography to outline the problem, on through the making of a mold of the socket by use of one of the alginate gels, down to the production of an acrylic resin blank to represent the sclera. An artist draws a reproduction of the fellow iris on paper, which is then accurately placed in a bed prepared in the sclera. Finally clear fluorescent acrylic polymer is prepared and is molded over the iris to represent the cornea. The final prosthesis is then polished, vessels painted on the sclera, and the prosthesis tried on the patient. Any

necessary small modifications can be made by grinding and polishing.

The acrylic material used is only slightly susceptible to etching by the eye-socket fluids or secretions. If scratched from handling, it may easily be polished. The prothesis is resistant to the usual accidental stresses, and, if a clean break occurs, can be repolymerized or the entire eye duplicated. Pictures of end results are given as well as descriptions of the various steps in the process. Owen C. Dickson.

Romagosa, J., and Rackley, G. D. **Orbital cellulitis with severe cerebral symptoms.** *New Orleans Med. and Surg. Jour.*, 1944, v. 97, Dec., p. 276.

This is the report of a case of severe orbital cellulitis possibly complicated by cavernous-sinus thrombosis. Although the prognosis at the outset seemed very grave, complete recovery followed therapy with sulfonamide drugs, penicillin, and later drainage of a supraorbital abscess. It is certain that this patient had severe orbital cellulitis with beginning extension backward into the cranial cavity and with possible thrombosis of the cavernous sinus. It is almost certain that without chemotherapy death would have occurred before localization of the infection and abscess formation could take place. It is difficult to evaluate the relative roles played by the sulfonamide drugs and penicillin in this case, since they were administered concomitantly. It should be noted, however, that marked improvement occurred after intravenous administration of sulfathiazole and before penicillin could be obtained.

Theodore M. Shapira.

Ruedemann, A. D. **Eye changes in disease of the thyroid.** *Jour. Lancet*, 1944, v. 64, Nov., p. 376.

The author presents a review of over

10,000 cases of thyroid disease. The fact that it may be only part of a polyglandular difficulty is stressed. Overaction of the thyroid, toxic thyroid, or hyperthyroidism is the only disturbance producing exophthalmos of a high degree. Colloid goiter and hypothyroidism, except when the basal metabolism is very low, affect to a lesser degree. Persistently wide palpebral fissures should make one suspicious of hyperthyroidism in either children or adults. Neurocirculatory asthenia must be ruled out by the result of bed rest, by rapidly falling basal rate, and so on. If the exophthalmos is bilateral or progressive, surgery to the thyroid is indicated. The duration of the exophthalmos prognosticates the amount of recession later, averaging about 2 mm. (Hertel). Muscle errors are common and persistent, and may require exercise or surgery. Corneal ulceration is infrequent and is due to exposure or some neuromuscular factor. Exophthalmos of hypothyroidism is bilateral and is associated with edema of the upper and lower lids.

TUMORS

Bruner, W. E. **Errors in diagnosis of intraocular tumors.** *Amer. Jour. Ophth.*, 1945, v. 28, March, pp. 297-302; also *Trans. Amer. Ophth. Soc.*, 1944, v. 42.

Goldsmith, A. J. B. **The effect of diathermy on a malignant melanoma of the choroid.** *Trans. Ophth. Soc. United Kingdom*, 1943, v. 63, pp. 88-94.

The author gives the histologic findings of the sarcomatous eye whose treatment with diathermy is reported by Williamson-Noble (see below under that name), and which was removed because of a large intraocular hemorrhage 27 days after the diathermy. A great part of the tumor was a necrotic mass. There was an area of active growth posteriorly and anteriorly. There were no blood vessels in the operative area. From the choroid in front of the tumor new capillary loops and fibroblasts were growing into the necrotic tumor mass. Two of the posterior ciliary vessels were thrombosed. The necrosis appeared recent and the author felt it was due to the diathermy and to loss of nutrition from thrombosis of the vessels.

The author concludes that complete destruction of a suitably placed choroidal growth of small size could be secured by diathermy coagulation, and that surface diathermy might be the safest method because of its avoiding dissemination. As many of the pigmented malignant tumors of neuroepithelial origin are radio-resistant, and large doses of radon, radium, or X rays would be necessary for effective treatment and damage to lens or retina might therefore result, he feels that diathermy, being almost entirely local in its effect on the blood vessels, is the method of choice once it has been decided not to enucleate the eye. (2 figures, references.) Beulah Cushman.

Williamson-Noble, F. A. The effect of diathermy on a malignant melanoma of the choroid. *Trans. Ophth. Soc. United Kingdom*, 1943, v. 63, pp. 85-86.

The author reports treatment of a sarcoma of the choroid with diathermy, in an eye without increased tension in

a woman 44 years of age. Three days later a large hemorrhage occurred. As vision did not improve, the eye was enucleated 27 days after the diathermy operation. (And see under Goldsmith above.) Beulah Cushman.

INJURIES

Heppel, L. A., Neal, P. A., Endicott, K. M., and Porterfield, V. T. Toxicology of dichloroethane. *Arch. of Ophth.*, 1944, v. 32, Nov., pp. 391-394.

This paper is concerned only with the peculiar action on the cornea of certain species of animals upon exposure to dichloroethane vapor in different concentrations. Eleven species of animals were used and four concentrations were employed; 3,000, 1,500, 1,000 and 400 parts per million parts of air. Each period of exposure was seven hours.

Exposure of dogs for seven hours to inhalation of dichloroethane in concentrations of 400, 1000 and 1500 parts per million led to bilateral swelling and turbidity of the corneas. Development of the turbidity was always bilateral, but the clearing process sometimes involved only one eye. When dogs were given repeated daily exposures to dichloroethane in a concentration of 1000 parts per million in series of five exposures and separated by rest periods of two days, they gradually became tolerant to the vapor. Eventually, no cloudiness developed after the exposures. Of eleven species of animals tested for sensitivity of the cornea to dichloroethane, namely, the rat, mouse, rabbit, guinea pig, hog, cat, raccoon, fox, dog, chicken and rhesus monkey, only the fox and the dog showed cloudy corneas. No cases of injury to the human cornea from dichloroethane

have been reported. (References, 2 figures.)

Hessberg, R. J. Problems of ophthalmology of modern warfare. *Vida Nueva*, 1944, v. 18, Oct., pp. 149-218.

This exhaustive article deals with the subject under many headings, some of which are as follows: physical capacity of the soldier and the problem of compensation for injuries caused by war; requirements for entering military service; emergency treatment; perforating lesions; the obligation of the soldier to submit to operation; gas gangrene; tetanus infection; sympathetic ophthalmia; fractures of the orbit; contusion of the posterior part of the eye and detachment of the retina; head injuries; lesions in the interior of the orbit; radiography for demonstration of bullets in the cranium; lesions of the brain; importance of campimetry; traumatic retinopathy; gas injuries; burns and blasting injuries; surgery of reconstruction; care and reëducation of war blind. (No illustrations, no list of references.)

W. H. Crisp.

King, E. F. Some observations in traumatic cataract. *Trans. Ophth. Soc. United Kingdom*, 1943, v. 43, pp. 76-83.

Operative interference should not be undertaken until the reaction to the original trauma has subsided. Preliminary treatment should be conservative. The sulfonamides should be used early with any suggestion of an exogenous infection, and protein shock therapy should be repeated if necessary until five doses have been given at three-day intervals. Secondary glaucoma can usually be controlled with mydriatics and heat in the form of short-wave diathermy.

The treatment of traumatic cataract

under optimum conditions depends somewhat on the condition of the second eye. The operation is technically easier if done within a few months or weeks of the original injury.

Operative interference is contraindicated if vitreous is in the anterior or posterior chamber, if there are anterior synechiae or thickened anterior capsule, and in patients past middle age unless intracapsular extraction is practicable. (One figure.)

Beulah Cushman.

McGuire, W. P., and Raffetto, E. C. Construction of a contact lens for localization of intraocular foreign bodies. *U. S. Naval Med. Bull.*, 1944, v. 43, Dec., p. 1239.

A method of manufacturing a contact lens, using materials at hand in a dental prosthetic department, is described. A matrix of pink dental base-plate wax is molded to fit inside the lids of a standard patient. The matrix serves both as a lid retractor and as a form for holding the impression material, which consists of an alginate base-powder type which when mixed with water forms an elastic gel. The retarder of a unit of this type is first placed in 75 c.c. of water at 70 degrees F. and dissolved. The powder is then added and spatulated, and the mass is applied to the anesthetized eye. The setting time is four minutes. The resulting impression is accurate and should show a definite corneoscleral junction. The impression is then fixed, a stone cast poured, a wax pattern made and a clear acrylic resin lens processed. This is polished and placed in the eye and the vertical and horizontal meridia marked with pencil at the corneoscleral margin. Silver amalgam alloy is packed into small holes drilled into the anterior surface of the

lens at the above points. The lens is then polished and is ready for use.

The technique of use is the same as that described by Pfeiffer after the original description by Comberg. This is briefly given in the article. Their exposure factors are current strength of 30 milliamperes at a distance of 30 inches and an exposure of $\frac{3}{4}$ second. The anteroposterior view is taken at 75 kv. and the lateral at 58 kv. All views are taken with a 60-cycle current and full-wave rectification. (Drawings of lens.)

Scherling, S. S., and Blondis, R. R. **Effect of chemical-warfare agents on the human eye.** *Arch. of Ophth.*, 1944, v. 32, Nov., pp. 381-387.

With the possibility of gas warfare, it becomes apparent that clinical investigation of chemical agents so employed and their effects on the human eye is of paramount importance. The material for this study consisted of personnel at a chemical-warfare arsenal. The authors report in detail representative cases of (1) injury from mustard gas vapor, (2) injury from liquid mustard gas, (3) injury from lewisite vapor, (4) injury from lewisite, (5) injury from thermate and (6) injury from white phosphorus lime.

From their study, the authors draw the following conclusions: Photophobia and blepharospasm are constant complaints. The bulbar conjunctiva appears to suffer more than does the tarsal conjunctiva. Staining of the corneal epithelium after exposure to mustard gas is rapid and punctate, indicating a keratoconjunctivitis rather than a conjunctivitis only. Mustard-gas vapor produces rather characteristic edema of the corneal epithelium, the appearance being greasy and the

process reversible. Absence of exudate and cells in the aqueous and of changes in the iris suggests that the products of corneal breakdown are not toxic if absorbed into the aqueous and that mustard gas does not pass unchanged through the cornea. Despite the fact that lewisite liquid and lewisite vapor have been proved to be as destructive to the skin as is mustard gas in corresponding form and dosage, the reported cases of contamination of the eyes show little serious effect. In none of these cases was there evidence of increased intraocular pressure.

The authors make the following recommendations: Homatropine is preferable to atropine since the corneal damage is transient and reversible. Casualties from vesicant agents need exist as such for only two days to two weeks, and the casualty time and the duration of symptoms and signs correspond to the clinical severity of the burn.

Use of glycerine, because of its hygroscopic effect, is recommended to combat the corneal edema that accompanies keratoconjunctivitis due to mustard-gas vapor. Contamination of the conjunctiva with particles of white phosphorus should be treated as elsewhere on the body surface, the medication including immediate use of a copper-sulfate solution. (2 tables, 2 photographs, references.)

SYSTEMIC DISEASES AND PARASITES

Carroll, F. D. The role of dental infection in diseases of the eye. Connecticut State Dental Assoc. Bull., 1944, Dec. 11, pp. 37-41.

The author considers which diseases of the eye may be almost certainly caused by dental infection, which may probably be caused by this factor, and which are definitely not due to it. In the first class he includes uveitis, episcleritis, and orbital inflammation; in the second class certain cases of blepharoconjunctivitis, keratitis, and macular disease; and among those never or almost never related to dental infection he places retrobulbar neuritis, senile cataract, and primary glaucoma. In slowly tracing down the etiology of one eye disease after another, the role of foci of infection has diminished. A sense of balance is essential in the evaluation of this medical problem. On the other hand, although dental infection is now considered an infrequent cause of eye disease, it may in any particular case be of great importance. (References.)

Hogan, M. J., and Cordes, F. C. Lipo-chondrodystrophy. Arch. of Ophth., 1944, v. 32, Oct., pp. 287-295.

Lypochondrodystrophy is a rare con-

genital disease characterized by chondrodystrophic changes in the skeleton and deposition of a lipid-like substance in many of the tissues, including the cornea. The disease is first noticed about the first year of life, when dorso-lumbar kyphosis and enlargement of the head become apparent. By the age of four years normal growth has largely ceased. The head is enlarged, and deformed by saddle nose, wide-set protuberant eyes, and thickening of lips and tongue. The abdomen is protuberant, with an umbilical hernia and enlargement of the liver and spleen. The joints of the extremities present deformities and limitation of motion. In over 75 percent of cases a distinct cloudiness of the corneas appears before the age of three years. The corneas have a ground-glass appearance and are diffusely hazy. The haze is produced by tiny gray or yellow-gray dots which eventually become distributed throughout the stroma.

The authors report the pathologic findings of three cases of this disease examined at autopsy. Two of the patients were brothers whose clinical findings had been reported previously. One of the children died at the age of 6½ years of pulmonary tuberculosis, one of a respiratory infection at the age of five and one of hydrocephalus at the age of five years. Detailed studies of the corneas were made to determine the cause of the haze. The corneal changes were found to be limited to the region of Bowman's membrane and to the corneal corpuscles. There was an infiltration of numerous large phagocytic cells into the region of Bowman's membrane, with thinning and rupture of the membrane. The corneal corpuscles were swollen. Both the phagocytic cells and the corneal corpuscles showed

numerous fine granules in their cytoplasm. These granules could be seen in frozen sections but could not be found in tissues prepared in fat solvents, an indication of their possible lipid nature. The granules, however, did not take the usual stains for fats. The findings of the authors closely correspond to those of two of the three other observers who have reported histologic examinations of eyes in lipochondrodystrophy. (7 illustrations, references.)

Isola, W., and Osimani, J. J. A new case of conjunctival ophthalmomiasis produced by *Oestrus ovis* in Uruguay. Arch. Uruguayos de Med., Cirugia y Especialidades, 1944, v. 25, Sépt., pp. 260-264.

The only case previously published in Uruguay was reported in 1925 by Gaminara. The present case was in a youth of 18 years, who gave the history that three days previously, while taking his siesta in the shade of a tree, he had been pestered persistently by an unusually large fly, which in spite of all his efforts succeeded in striking his right eye. He had no immediate discomfort, but the next day had a definite sensation of a foreign body in the right eye, with which was associated mild irritation of the conjunctiva.

The patient discovered the presence of a small "worm" which wriggled vigorously in the conjunctival sac; he removed it easily. In the course of the same day he was able to extract four new "worms." Two days later medical examination disclosed the presence of two more larvae, each about 1 mm. long, one adherent to the tarsal conjunctiva and the other to the upper bulbar conjunctiva. Microscopic study

indicated that the larvae were of the species *Oestrus ovis* L. The authors confirm the opinion of Gailliard that the monograph by the Russian author Portchinsky is erroneous in showing "thorns" on the abdominal instead of the dorsal surface of the larvae. Special attention is called to the characteristic tenacity of *Oestrus ovis* in making its deposit of eggs; such characteristic having been noted in previously reported cases. (References.) W. H. Crisp.

HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Anson, B. J. Conceptions of structure, function, and diseases of the eye in the collected works of Ambrose Paré. Quarterly Bull. Northwestern Univ. Med. School, 1944, v. 18, no. 3, pp. 244-255.

Organs were considered hollow tubes or pulpy masses. A bodily organ was said to be able to exert a normal action when the vaporous spirit or pneuma was strong and pure, and was assisted by a proportionate mixture of four essential juices, termed humors. If the spirit became weak or the humors degraded either by the direct effect of heat or cold, or by deleterious aerial particles, the organs were diseased. The doctor cleared the organs of humoral wastes by blood-letting, and strengthened the spirit by dietary means.

The eyes were said to be composed of six muscles, five coats, three humors, and "a most bright spirit"; furthermore, of two nerves, a double vein, and one artery. The visual spirit enclosed

in the eye was described as transmitting a physical image of the environmental scene through the humors along the canalized optic nerve to the ventricular headquarters of the spirit. In the ventricles the spirit was stored and refined, and sent or received by way of the hollow nerves. (2 figures.)

R. Grunfeld.

Biram, J. H., and Barton, P. N. Vision and accident repeaters. *Indust. Med.*, 1944, v. 13, Sept., p. 683.

Two control groups and one accident-repeater group totalling 280 employees were studied, using the American Optical Company's industrial visual testing device with vectograph target. Lack of binocular vision was found in 10 percent of the accident-repeater group, and in 3.3 percent of control groups 1 and 2. Distant depth perception was below normal in 46.6 percent of the accident repeaters. On applying these percentages to preplacement candidates one would lose 4.4 good candidates for each accident repeater eliminated, an increase in rejection rates of 26.5 percent of all preplacement candidates.

A similar study of the horizontal phorias revealed that 15 out of every 100 accident repeaters would be eliminated, with a loss of 42 nonaccident-repeaters. This would increase the rejection rate percentage 8.1 percent.

Although there is some correlation between certain visual defects and the accident-prone worker, these factors alone do not justify rejection of a worker for a hazardous job. It is suggested that with the above there should be combined dexterity tests and other psychologic tests, although these alone have not proved too successful in determining job placement.

Carr, E. F. Bibliography of early ophthalmological works in the Archibald Church Library. *Quarterly Bull. Northwestern Univ. Med. School*, 1944, v. 18, no. 3, pp. 238-243.

The author enumerates and comments upon the rare books on ophthalmic subjects, 32 in number, to be found in the Archibald Church Library. Three of the rare books were printed in the 16th, 5 in the 17th, and the rest in the 18th century. (10 illustrations.)

R. Grunfeld.

Chance, Burton. Johannes Müller. *Arch. of Ophth.*, 1944, v. 32, Nov., pp. 395-402.

Johannes Müller, a German doctor of the 19th century, is chiefly notable in the field of ophthalmology for his observations on the mechanism of sight. His principal contributions were his explanations of color sensations caused by pressures on the globe, "pressure phosphenes"; of the adaptation of the eyes for sight at different distances; of single vision with two eyes; of the cause of single vision; and of phenomena of double vision.

Of greatest value was Müller's comprehension of binocular vision. He observed that in normal eyes the movements of the eyes would always cause the images to fall directly on corresponding parts of the two retinas, producing single vision. If, on the contrary, from various causes the images fell on noncorresponding points, double vision resulted. Müller assumed that single vision was effected by the passage of similar fibers from these points to the brain, which became united and gave rise to the consciousness of a single object.

Müller, in spite of his greatness, did not make any discovery in ophthalmology.

mology of the highest rank, but he did investigate and turn to the best account what others had discovered. (One reference, 9 figures.)

Gover, M., and Yaukey, J. B. Defective vision as determined by the Snellen test, and other chronic conditions. Public Health Reports, 1944, v. 59, Sept. 8, pp. 1171-1184.

The Farm Security Administration organized clinics for examination of members of white and Negro borrower families residing in 11 Southern States and six Northern or intermediate States. These families represent a low-income farm population and the researches were made in connection with a rehabilitation program. Curves of age prevalence of defective vision as determined by the Snellen test are presented. These show less defective vision than urban groups, especially between the ages of 20 and 45 years. Defective vision is less frequent among Negroes than whites for both male and female groups in practically every locality. White females have more defective vision than white males, and among the Negroes the same proportion is noted, for every age group. The incidence of pterygium is higher among white males. Negroes have higher rates than whites for cataract, whites have higher rates for strabismus and trachoma. Outstanding are the high prevalence of cataract in Florida and of trachoma or suspected trachoma in Arkansas. (References.)

R. Grunfeld.

Riemer, H. B. Topographic and etiologic study of 1,176 indigent blind

persons in Massachusetts. *Arch. of Ophth.*, 1944, v. 32, Oct., pp. 304-307.

In the past it has been very difficult to obtain any indication of either the number of blind persons or the causes of blindness in a community. The Federal Social Security Board, in extending aid to the states for care of the indigent blind, has insisted that blind applicants be examined by competent ophthalmologists and that records be kept of the defects found. This has made it possible to obtain reliable statistics on the causes of blindness among the indigent.

The author reviews the findings in 1,176 cases of blindness in the state of Massachusetts. The data are summarized in three tables giving the topography and type of disease, an etiologic classification, and the age at onset of blindness. Glaucoma, with 111 cases, headed the list of diseases involving the eyeball, and myopia was second with 100 cases. There were 38 cases of blindness due to structural anomalies of the globe. Corneal disease was responsible for 187 cases and diseases of the iris and ciliary body for 100. There were 18 cases of sympathetic ophthalmia. Lens abnormalities were responsible for 181 cases. Involvement of the choroid and retina caused blindness in 217 cases, of which there were 60 of chorioretinitis, 59 of retinal degeneration, 37 of retinal hemorrhage, 29 of arteriosclerotic disease, and 25 of separated retina. In 205 cases blindness was caused by disease involving the optic nerve and visual pathway.

Infectious diseases produced blindness in 376 cases, of which syphilis was responsible for 128. Trauma, including chemical burns, accounted for 61 cases. In 13 cases blindness was due to poisoning and in 18 to neoplasm. Gen-

eral diseases were responsible for 93 cases, of which diabetes produced blindness in 45 and vascular disease in 40. In 152 cases blindness was due to conditions of prenatal origin, including 141 cases of retinitis pigmentosa.

Statistical studies of the causes of blindness form the basis of any real program of prevention. The present study emphasizes the following needs: Enforcement of all laws enacted for the control of infectious disease; more care in reporting causes of blindness; early detection of glaucoma and diabetes; prevention of injuries; authentic data on cases in which blindness is hereditary; adequate measures to assure proper medical care so as to prevent onset of blindness. ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Stone, L. S. Functional polarization in retinal development and its reestablishment in regenerating retinæ of rotated grafted eyes. *Proc. Soc. Exper. Biol. and Med.*, 1944, v. 57, Oct., p. 13.

Because of the regenerating faculty of adult salamander eyes after interruption of either nerve supply or blood supply, or after total transplantation, interesting experimental work on orientation of spatial localization is possible. Rotation of an eye through 180 degrees without interruption of the nerve or blood supply totally reversed the direction of motor activity resulting from visual stimuli, indicating definite quadrantic localization of visual and tectorial stimuli. Restora-

tion of the eye to normal position restored the usual visuomotor responses.

Rotation of an eye 180 degrees after excision, in which regeneration of the retina was necessary before vision returned, revealed the same reversal of quadrantic localization as in simple rotation without excision. Experiments are under way on larval and embryonic stages to determine the time at which retinal spatial differentiation is established. So far rotation of the cup in embryos results in no alteration in normal orientation.

Owen C. Dickson.

Sverdlitch, J. Influence of the hypophysis and the suprarenal gland upon retinal pigment in "*Bufo arenarum*" Hensel. Reprint of paper presented to Sociedad Argentina de Biologica, June 11, 1942.

The author describes a series of experiments upon these frogs. After ligation of some of the principal arteries, Ringer's fluid is carried into the circulation, replacing the blood stream. When the Ringer solution is clear, Held's fixation fluid is introduced, so as to fix the organs and tissues of the cephalic region. The method was applied to 54 animals, and 108 eyes were studied histologically. Some frogs were used as controls, some after removal of the hypophysis, some after removal of the suprarenals.

It was found that the retinal pigment in this frog expanded in light and retracted in darkness. After removal of the hypophysis, illumination produced moderate retraction, although less than in the control animal exposed to darkness. After injection of extract of the posterior lobe of the hypophysis, illumination caused complete expansion of the pigment in the hypophysectomized animal, but there was no effect

in darkness. The suprarenal gland did not appear to have any physiologic effect on the reactions to light and darkness. Adrenalin expanded the pigment after exposure to either light or darkness.

W. H. Crisp.

Vidal, F., and Ma'brán, J. L. Arrangement of the myelinic fibers in the optic tract of the cat. Arch de Oft.-de Buenos Aires, 1942, v. 17, Dec., p. 733.

In 24 cats of different ages, retinal microlesions were produced and one or both eyes enucleated after a period of time ranging from nine days to ten months. The specimens were studied with the Weil and Marchi technique as modified by Zwank-Davenport. On the basis of this experimental work it is concluded that the degenerated primary fibers of the optic tract end or lose their identity in the zone of the ventral geniculate body. Enucleation of one eye showed the number of crossed fibers to be greater than the number of homolateral fibers. Osmium tetroxide stain showed the optic fibers to be arranged in two bundles: (a) the larger bundle, occupying the lateral portion; (b) the smaller bundle, occupying the medial border. The homolateral fibers run along the external border of the tract. The retinal microlesions produced by catholysis and studied with the osmium-tetroxide stain show that the inferior homolateral fibers run along the external border of the tract, while the superior homolateral fibers are situated toward the medial border. (Photomicrographs, bibliography.)

Warkany, J., and Schraffenberger, E. Congenital malformations of the eyes induced in rats by maternal vitamin-A deficiency. Proc. Soc. Exper. Biol. and Med., 1944, v. 57, Oct., p. 49.

The occurrence of anophthalmos and microphthalmos in pigs whose mothers had been fed a diet deficient in vitamin A has been demonstrated. The authors have developed what they term "open eyes" in three still-born litters of experimental rats which had been fed diets deficient in vitamin A. Nine of the other mothers in the series resorbed their embryos, the three previously mentioned being the only ones to carry their litters toward term.

In the abnormal "open eye" there is *no clear differentiation of lids and cornea*, and the anterior chamber is present in a rudimentary form only. In the normal eye the vitreous can be seen between the lens and the retina, where-

as the same space in the abnormal eye is filled with connective tissue. The retina of the abnormal eye is folded and disorganized. In the closed abnormal eye the lids are fused with the cornea, and the anterior chamber appears as a linear space between the thick membrane thus formed and the lens. In several specimens a cleft can be seen in the inferior part of the retina, and a strand of connective tissue penetrates this cleft and spreads out in the space between the lens and the retina. *This cleft represents a coloboma of the retina.* No such abnormality was present in control series. (Microscopic pictures shown.)

Dr. Emil H. Webster, Sault Sainte Marie, Michigan, died January 19, 1945, aged 75 years.

MISCELLANEOUS

The American Board of Ophthalmology will hold an examination at Los Angeles in January, 1946, at the time of the Mid-Winter Course.

Applications for this examination must be filed before September 1st.

For details prospective candidates should write at once to Dr. S. Judd Beach, Secretary, Cape Cottage, Maine.

Formation of The Eye Bank for Sight Restoration, Inc., which will collect and preserve healthy corneal tissues from human eyes for transplanting to blind persons who have lost their sight because of corneal defects, was recently announced. The organization, national in scope, has been incorporated under the laws of New York State, and 22 leading hospitals in

New York City are now affiliated with it. In addition, 20 outstanding ophthalmologists throughout the country will serve in an advisory capacity. Headquarters are at 210 East 64th Street, New York City.

The officers are Stanley Resor, president; Dr. R. Townley Paton, vice-president; Cyril B. Hartman, secretary; Walter C. Baker, treasurer; and Mrs. Henry Breckinridge, executive director.

It has been announced by the National Society for the Prevention of Blindness that Dr. Willis S. Knighton, New York, will serve as chairman of the Committee on Glaucoma of the National Society for the Prevention of Blindness, succeeding the late Dr. Mark J. Schoenberg. Additions to the Committee on Glaucoma include Major Fred Heflinger, superintendent, and Dr. F. L. P. Koch, chief of the Glaucoma Clinic, Manhattan Eye, Ear, and Throat Hospital, New York City.

The sixth annual William Thornwall Davis Postgraduate Course in ocular surgery, pathology, ocular motility, and orthoptics will be given at the George Washington University School of Medicine, Washington, D.C., May 28-June 2, 1945. The Army Institute of Pathology, directed by Col. J. E. Ash, MC, A.U.S., will give the course in eye pathology as has been done in former years. The surgery, ocular motility, and orthoptics will be given by the resident staff of the Department of Ophthalmology under the direction of Dr. Ernest Sheppard, Professor of Ophthalmology. The course is limited to 30 registrants.

The program for the coming meeting of the Pan-American Congress of Ophthalmology, which is to be held in Montevideo, Uruguay, the week of November 25, 1945, is practically completed, and will be published in the very near future. As was done at the last Congress, all papers will be in Spanish, Portuguese, or English, with projected translations as the paper is being presented.

Any recognized ophthalmologist is eligible for membership. The annual fee is \$5.00, payable to Dr. Conrad Berens, Treasurer, 218 Second Avenue, New York 3, New York. That fee entitles the member to receive gratis the official organ of the Congress, "Ophthalmologia Ibero Americana," which is a quarterly trilingual abstract journal.

Tentative travel arrangements are being made with the Pan-American Airways, as well as the American Express Company, but these cannot be concluded definitely until there has been a further turn in world affairs.

The fourteenth semi-annual postgraduate conference in neuromuscular anomalies of the eyes was held at the Children's Memorial Hospital at Chicago, Illinois, by George P. Guibor, M.D., from May 6th to 11th, inclusive. Among the guest lecturers were Drs. Hendrie W. Grant, Aubrey Pember, and Avery Prangen.

The John O. McReynolds Lectureship was inaugurated April 6th by Dr. James W. White of New York who spoke on "Treatment and prevention of neuromuscular eye defects." This lecture was established at the University of Texas Medical Branch, Galveston, by Col. and Mrs. Frank W. Wozencraft, who were among the honor guests.

SOCIETIES

The forty-second meeting of the Reading Eye, Ear, Nose, and Throat Society was held in Philadelphia, Wednesday, February 21, 1945. The Eye Section attended medical and surgical clinics and a lecture by Dr. Wilfred E. Fry, at Wills Hospital.

The Brooklyn Ophthalmological Society held its regular meeting on April 19th at the Towers Hotel. The following scientific program was presented: "Hypertension and retinal vascular disease" by Dr. William Dock, discussed by Dr. Edwin P. Maynard with re-

gard to medical aspects and Dr. John N. Evans with reference to ophthalmologic aspects; and "A clinical study of the effect of tobacco inhalation on the normal angioscotoma" by Dr. Austin I. Fink.

At the March 27th meeting of the Milwaukee Oto-Ophthalmic Society Dr. Peter C. Kronfeld of Chicago spoke on "Causes of failure of anti-glaucomatous operations."

The Los Angeles Society of Ophthalmology and Otolaryngology appointed the following officers for 1945: Dr. Orrie E. Ghrist, president; Dr. Alfred R. Robbins, vice-president; and Dr. K. C. Brandenburg, secretary-treasurer. Meetings take place at the Los Angeles County Medical Association Building, 1925 Wilshire Boulevard, Los Angeles, on the fourth Monday of each month from September to May, inclusive.

The Association for Research in Ophthalmology has canceled its 1945 meeting in cooperation with the war-travel and convention program. Essayists are requested to reserve their manuscripts for a possible meeting in 1946, in conjunction with the convention of the American Medical Association.—Brittain F. Payne, Lt. Colonel (MC), Secretary-Treasurer, AAF School of Aviation Medicine, Randolph Field, Texas.

The annual Congress of the Ophthalmological Society of Egypt was held at the Memorial Ophthalmic Laboratory, Giza, Egypt, on March 15th and 16th. Included in the program was a symposium on "Proptosis."

*Pontocaine
Hydrochloride*

in

OPHTHALMOLOGY

and in

RHINOLARYNGOLOGY

*Surface Anesthetic
with Prolonged Effect*

Dependable anesthesia
of the mucous membranes

is readily obtained by the topical application of Pontocaine hydrochloride. This widely used agent acts quickly, penetrates deeply, and gives prolonged anesthesia. A variety of operative and nonoperative procedures on the eye, nose and throat may be successfully carried out with small quantities of relatively weak solutions.

HOW SUPPLIED: For surface anesthesia in ophthalmology: 0.5 per cent solution in bottles of ½ oz. and 2 oz.

For surface anesthesia in rhinolaryngology: 2 per cent solution in bottles of 1 oz. and 4 oz.

SYMPATHETIC OPHTHALMIA FOLLOWING SUBCONJUNCTIVAL RUPTURE OF THE EYEBALL*

CHARLES A. PERERA, M.D.

New York

Sympathetic ophthalmia has been recognized for at least 250 years. Randolph,¹ in an excellent historical review, showed that the disease was known in the latter part of the seventeenth century by Thomas Bartholinus, and later by Bidloo, Le Dran, Beer, and Demours. The last-named was the first physician in France who called attention to this malady and undoubtedly recognized it as early as 1818. Hirschberg² recorded that von Ammon, in his prize essay on iritis, in 1835, described two cases of sympathetic inflammation following injury and warned oculists to watch for this disease in cases of traumatic iritis of one eye. Mackenzie described sympathetic ophthalmia exhaustively in his textbook in 1844.

Sympathetic ophthalmia is a serious disease of the eyes, and fortunately very rare. Duke-Elder³ estimated that it occurs in about 0.1 to 0.15 percent of clinic patients, and in about 90 percent of the instances follows perforating wounds of the eyeball or intraocular operations. A survey of the literature by R. Irvine,⁴ in 1940, showed that sympathetic ophthalmia followed perforating wounds of the globe in 1 or 2 percent of the cases. Sta-

tistics on the incidence of sympathetic ophthalmia recorded by many authors show that 25 to 40 percent of the examples are associated with operations upon the eyeball. The disease occurs at all ages, and is found predominantly in males. Sympathetic ophthalmia has been described in cases of necrotic malignant melanoma of the uveal tract, following perforating ulcers of the cornea, and as an aftermath of contusion of the eyeball with subconjunctival rupture of the globe. Most of the few examples of sympathetic ophthalmia following contusion without rupture of the eyeball are open to doubt. The case of Delaney,⁵ reported in 1931 as an instance of sympathetic ophthalmia unassociated with perforation or rupture of the eyeball, cannot be considered as correctly diagnosed, since the pathologic report by Major George Callender of the Army Medical Museum showed no evidence of the microscopic findings typical of sympathetic ophthalmia. In spite of the pathologist's report, the author concluded that this case was one of sympathetic ophthalmia because all medical investigations were negative. Lamb,⁶ in 1932, reported an example of typical sympathetic ophthalmia in a six-year-old girl following nonperforating trauma. Joy,⁷ in his analysis of 41 cases of sympathetic ophthalmia in 1935, included two instances in children following airgun injuries, the injured eyes pre-

*From the Department of Ophthalmology, College of Physicians and Surgeons, Columbia University, and the Institute of Ophthalmology, Presbyterian Hospital, New York. Candidate's thesis for membership in the American Ophthalmological Society, June, 1944.

senting hyphema and no rupture of the globe. Trowbridge⁸ recorded in 1937 a case of sympathetic ophthalmia as following a superficial injury by a piece of wood. Andersson,⁹ in 1938, reported such a case in a child, only to find a tiny perforating wound of the sclera, choroid, and retina in a study of serial microscopic sections of the enucleated globe. Complete studies of sympathetic ophthalmia within the past 40 years have been made by E. Fuchs,¹⁰ Gilbert,¹¹ Theobald,¹² Joy,⁷ Woods,¹³ D. H. Trowbridge,⁸ Gördüren and Sohr,¹⁴ and R. Irvine.⁴

The etiology of sympathetic ophthalmia is still unknown, but two main theories are favored: (1) ectogenous infection, and (2) allergy, probably to uveal pigment. Tuberculosis as a cause is becoming less tenable. Holst,¹⁵ in 1941, reported five examples of sympathetic ophthalmia in healthy children following penetrating injuries of the eyeball. Since all these youngsters gave a negative response to intradermal tuberculin tests, the author concluded that these cases could not have been caused by the tubercle bacillus. H. Gifford¹⁶ and A. Fuchs¹⁷ were among the proponents of the theory of ectogenous infection by microbes or virus. Elschnig¹⁸ introduced in 1910 the conception that sympathetic ophthalmia is due to antigenic resorption of uveal tissue from injury or disease, thence to the hypersensitivity of the remaining portion of the uvea of the primarily diseased eye which were not influenced by the trauma, and primary inflammation as well as hypersensitivity of the normal uvea of the second eye. This theory was supported by Elschnig's co-workers, Salus¹⁹ and Bail,²⁰ and in the excellent papers of J. S. Friedenwald²¹ and Woods.^{13, 22} Gill²³ reported his findings to be consistent with the uveal-pigment-sensitivity theory.

The pathologic description of sympathetic ophthalmia was revealed by the classic studies of E. Fuchs.¹⁰ At the present time, pathologists recognize a characteristic histopathologic appearance in sympathetic ophthalmia, and differentiate this from the findings in ocular tuberculosis and other types of chronic uveitis. The main features in sympathetic ophthalmia in examinations of microscopic sections of the involved eyeballs are small round-cell and epithelioid-cell infiltration of the uveal tract, giant cells in the infiltrated areas, and varying amounts of pigment phagocytosis by the epithelioid cells. There is often a considerable infiltration in the region of the injury or operation. Eosinophils and plasma cells may compose a part of the infiltrate. A plastic exudate is frequently present. The iris is rarely if ever involved alone. Its posterior layers are first infiltrated with lymphocytes and later with epithelioid cells. The ciliary body shows involvement mainly in the vascular layer. The choroid usually reveals early infiltration in the layer of large blood vessels. The choriocapillaris is the least-involved layer of the choroid. The pigment epithelium often discloses excrescences made up of epithelioidlike proliferations, known as Dalen-Fuchs nodules. The remainder of the retina is not a further participant in the inflammatory process except for round-cell infiltration of the walls of the blood vessels in some cases. The sclera often contains lymphocytes in the lamina fusca and in the emissaria. Weigelin²⁴ confirmed Fuchs's findings and added descriptions of 17 cases from the Tübingen University Eye Clinic. Samuels^{25, 26, 27} further clarified the microscopic picture of sympathetic ophthalmia and showed that the characteristic infiltration in this disease develops in three stages: (1) lymphocytic infiltration in and around the walls of the large veins of the choroid,

(2) the formation of typical nodules containing giant cells in the center, surrounded by epithelioid cells and lymphocytes, and (3) the stage of formation of tumor-shaped masses of granulation tissue composed of the aforementioned cells.

The diagnosis of sympathetic ophthalmia is made in view of the history and clinical course of the specific plastic uveitis, in conjunction with the characteristic pathologic picture on study of sections of the enucleated eye. Without a pathologic examination, the identification of sympathetic ophthalmia may be correct, but is not proved and must be considered as presumptive. It is possible to have proved sympathetic ophthalmia, from a histologic point of view, in an injured eye or one operated on, with no evidence of uveitis in the uninjured eye. Trowbridge⁸ found two examples in his series.

Schirmer,²⁸ in his classic study of sympathetic ophthalmia in 1892, emphasized the need for critical study of the cases reported in the literature. He found that many examples diagnosed as sympathetic ophthalmia were improperly classified. Of 21 records of sympathetic ophthalmia following subconjunctival rupture of the globe, only 6 could be considered as valid instances, and 2 of these could be questioned.

This study was prompted by my investigations of a patient with sympathetic ophthalmia following a subconjunctival rupture of the eyeball. I have reviewed the available literature dealing with this rare combination and have listed the reported cases. It seemed logical and reasonable to exclude instances in which a surgical procedure had been carried out subsequent to the injury and preceding the onset of specific inflammation of the uninjured or sympathizing eye. I have also rejected examples of sympathetic ophthalmia following rupture of the sclera in which the lens, iris, or both of

these structures have been lost, as well as those cases in which the conjunctiva has been visibly torn. A few reports in the literature, such as those of Mooren,²⁹ Seidel,³⁰ and Rønne (quoted by Jensen³¹) give details which are inadequate for a well-grounded diagnosis. Joy,⁷ in his series, included a case of subconjunctival rupture of the globe with a mild sympathetic ophthalmia five weeks after the injury, but the data given were too scanty to warrant inclusion in the list below.

CASE REPORTS FROM THE LITERATURE

The following group of cases are presumptive or proved cases of sympathetic ophthalmia following subconjunctival rupture of the eyeball which have been reported.

1. Reported by Jacob³² in 1874.

A farmer was accidentally struck in the right eye by the finger of a person who was accosting him. The vision of the injured eye was immediately blurred. The left eye became inflamed seven weeks later, resulting eventually in a blind left eye, with adherent pupil, tremulous iris, and cataract. The author's examination of the patient's right eye at a later date showed the lens dislocated beneath the bulbar conjunctiva above and nasally, no trace of iris, a retina which was in good condition, and useful vision with the aid of a convex lens.

2. Reported by Ayres³³ in 1876.

A man, aged 38 years, ran against a pump handle, striking his right eye. The vision of this eye was immediately reduced to light perception. The vision of his left eye began to fail six weeks later, with pain in both eyes. Examination of the right eye showed an indirect rupture of the sclera, extending around the globe nasally. There was bluish-black hemorrhagic material beneath the bulbar con-

junctiva nasally, and the lens was seen as a rounded elevation under the conjunctiva anterior to the caruncle. The anterior chamber was deep. A small segment of iris was seen inferiorly. The media were turbid. Vision was equal only to detect hand movements. The left eye showed a dense pseudomembrane in the pupil, a shallow anterior chamber, complete posterior synechia, ciliary injection. The patient was hospitalized. Atropine was instilled into each eye three or four times a day. The vision of the injured eye improved to 15/40 by four months after the accident. The intraocular pressure of the left eye increased, with iris bombé and increased congestion. Iridectomy was performed on the left eye, with normalization of the intraocular pressure and disappearance of the ciliary injection. The vision of the left eye was practically nil.

3. Reported by Ayres³⁴ in 1882.

The patient was a man, aged 50 years, whose left eye was struck by the handle of a shovel or his own thumb. This eye sustained a subconjunctival rupture of the sclera, the wound being half an inch long, irregular, and directed upward. The anterior chamber was filled with blood. The vision of his right eye began to fail five weeks after the injury, and sympathetic iridocyclitis of the right eye was diagnosed. The patient was hospitalized for 2½ weeks and treated with atropine instillations and hot poultices. Examination 2½ months after the injury showed the vision of the left eye to suffice only for counting fingers at 3 feet. A grayish mass was seen in the vitreous. The vision of the right eye was 20/100. The right eye revealed moderate dilatation of the pupil, a posterior synechia downward and inward, and edema of the nerve head. One month later, the vision of the right eye had improved to 20/30. The condition

of the right eye gradually ameliorated until its vision became normal. The left eye finally cleared, with vision equal to counting fingers at 14 feet with a +9.00D. sph., absence of the iris, and a reduction in the size of the vitreous coagulum.

4. Reported by Gunn³⁵ in 1887.

A man, aged 58 years, had the left eyeball ruptured by a cow's horn. The lens was dislocated beneath the conjunctiva in the upper inner ciliary region. The right eye became injected and its vision misty six weeks after the injury. There were posterior synechiae of the right eye. The left eye was enucleated. Vision of the right eye was 20/50, 11 months after the injury. Pathologic study of the left eye showed: lens in its capsule beneath thickened conjunctiva in the upper nasal ciliary region; iridodialysis opposite the site of the scleral rupture, which was closed with tissue not unlike the thickened conjunctiva over the lens; a small hyphema; a deep anterior chamber; and generalized thickening of the ciliary body and choroid.

5. Reported by Deutschmann³⁶ in 1889.

The patient was a woman, aged 40 years, whose right eye suffered a subconjunctival rupture of the globe from an injury by a cow's horn. The sight of the injured eye was lost immediately. Examination of the right eye revealed a subconjunctival rupture of the sclera superiorly, with iris prolapse beneath the conjunctiva and bloody exudate in the anterior chamber. The left eye became inflamed four weeks after the injury, and the vision of this eye became impaired one week later. Enucleation of the right eye was performed six weeks after the injury. At that time the left eye had vision of 20/200 and showed ciliary injection and fine posterior synechia. There was

little change in the left eye two months later.

6. *Reported by Sachs³⁷ in 1889.*

The patient, 48 years of age, suffered a scleral rupture of the left eye in the ciliary region, with subconjunctival dislocation of the lens and iris nasally, and incarceration of the ciliary body in the scleral wound. The subconjunctival elevation measured 8 by 3 mm. The right eye became inflamed seven weeks after the injury, and was found to have iritis. The left eyeball was removed 8½ weeks after the accident, and the iritis of the right eye subsided three weeks later.

7. *Reported by Knapp³⁸ in 1891.*

The left eye of a man, aged 45 years, was bumped by the head of a small pet dog. Examination of this eye 10 days later showed subconjunctival hemorrhages, an elevation beneath the nasal bulbar conjunctiva produced by a dislocated iris, intact conjunctival and corneal surfaces, a 3- to 4-mm. rupture of the sclera nasally, iris absent from the interior of the eye, lens in place, some blood in the lower vitreous, and visual acuity of 15/200. The right eye had always been weak, and its vision was 20/70 with a convex lens. The right eye became inflamed 25 days after the injury, with reduction of visual acuity. A progressive plastic uveitis of the right eye developed, with remissions and relapses, finally leaving vision of 1/200 and a pupil closed by a dense gray pseudomembrane. The vision of the injured left eye was 2/200 seven months after the accident.

8. *Reported by Wadsworth (in discussion of Knapp's case) in 1891.*

A boy, aged 12 years, suffered a subconjunctival rupture of the sclera in the ciliary region from an injury by a spitball

projected from a toy gun. The uninjured eye became inflamed about three weeks after the accident. The injured eye was removed four weeks after the injury, but the sympathetic uveitis progressed to loss of vision of the patient's remaining eye.

9. *Reported by Meyer³⁹ in 1896.*

The patient was a woman aged 43 years, whose right eye was injured by a cow's horn. This eye was painful and inflamed, but quieted after several weeks, only to flare up again 10 months later. At this time, the left eye became painful, and the patient suffered from headache around this eye, and pain on attempting to read. Examination, 11 months after the injury, showed a shrunken right eye, with a scleral scar nasally, ciliary injection, an atrophic greenish-yellow iris, pupillary posterior ring synechia, and organized vascularized exudate in the lower pupil and in the posterior chamber. The left eye disclosed punctate deposits on the posterior cornea and on the anterior lens capsule, no posterior synechia, and a clear vitreous. Complete physical examination of the patient was negative. The right eye was immediately enucleated; rapid clearing of the intraocular inflammation of the left eye ensued and restoration of its vision to 6/6. Pathologic study of the right eye revealed infiltration beneath intact conjunctiva over a scleral wound in which iris was incarcerated, shallow anterior chamber, exudate extending from scleral wound to posterior chamber, hematogenous pigment and necrotic tissue under the conjunctiva and in the scleral rupture, young granulation tissue with some giant cells on the anterior lens capsule, infiltration of the ciliary body with dispersal of its pigment, thickening of the choroid, and detached retina. Coccuslike bodies were seen between the corneoscleral margins of the wound. This

globe showed a combined plastic and purulent iridocyclitis and choroiditis, indicative of a chronic and a recent inflammatory process.

10. Reported by Donaldson⁴⁰ in 1897.

A woman, aged 33 years, struck her right eye against the latch of a door. Examination of the injured eye showed a soft globe, a bluish swelling under the intact bulbar conjunctiva superiorly, blood in the anterior chamber, and vision of light perception. The left eye was normal. The right eye became painful, and there was bulging of the scleral wound. Enucleation was done 20 days after the accident. The microscopic study of the right eye disclosed a plastic cyclitis. The uninjured left eye became inflamed 47 days after the accident and 27 days after the removal of the injured right globe. The left eye had deposits on the anterior lens capsule. Physical examination of the patient gave normal findings. The woman was followed for five years during which her left eye suffered from recurring attacks of uveitis, worse after a bout of "catarrhal ophthalmia" which occurred three years after the injury and which left corneal scars. The vision of the left eye was 4/60 five years after the accident to its fellow eye.

11. Reported by Fuchs¹⁰ in 1905.

The patient was a man, 33 years of age. One of his eyes was injured by a cow's horn. The sclera was ruptured and the lens was dislocated beneath the intact bulbar conjunctiva at the site of the rupture. Sympathetic uveitis began in the uninjured eye six weeks after the accident. Enucleation of the ruptured globe was performed seven weeks after the injury occurred. Pathologic study of the removed eye showed typical sympathetic ophthalmia.

12. Reported by Fuchs¹⁰ in 1905.

The patient was a woman, aged 56 years, who suffered a subconjunctival dislocation of the lens from an injury by a cow's horn. The uninjured eye became inflamed six weeks after the injury, and the ruptured globe was enucleated several days later. It showed characteristic sympathetic ophthalmia on microscopic examination.

13. Case of Dimmer reported by Fuchs¹⁰ in 1905.

The microscopic sections of the enucleated eyeball showed a subconjunctival scleral rupture. The iris which lay beneath the conjunctiva was more heavily infiltrated than the uvea in the eye.

14. Reported by Weigelin²⁴ in 1910.

The patient was 41 years of age. One eye was injured by a cow's horn. The damaged eye suffered a subconjunctival rupture of the sclera, with dislocation of the lens beneath the conjunctiva, and traumatic aniridia. Sympathetic uveitis of the fellow eye began 44 days after the injury, and enucleation of the injured globe was carried out three days later. Pathologic study of microscopic sections of the removed eye showed rupture of the sclera superiorly, with lens and iris lying beneath the conjunctiva. The subconjunctival mass was heavily infiltrated with small round cells. The infiltration extended around the lens and contained epithelioid cells and round cells. The ciliary body and choroid showed lymphocytic infiltration with sparse epithelioid and giant-cell deposits. Vessels extending through the sclera showed perivascular infiltration with lymphocytes.

15. Reported by Weigelin²⁴ in 1910.

The patient, 61 years of age, suffered an eye injury by a cow's horn, with en-

suing subconjunctival rupture of the sclera and subconjunctival dislocation of the lens. The entire iris lay beneath the conjunctiva outside the globe. Sympathetic inflammation of the fellow eye began four months after the injury, and the hurt eye was removed seven days later. Microscopic study of this eye showed the subconjunctival mass to be heavily infiltrated with lymphocytes, epithelioid cells, and some giant cells. The intraocular tissues revealed only moderate infiltration of the ciliary body and choroid.

16. Reported by Hussels⁴¹ in 1914.

The patient suffered an injury of the left eye from a cow's horn. The right eye became inflamed five weeks later, and the left eye was then enucleated. Studies of microscopic sections of the removed globe showed typical sympathetic ophthalmia. The right eye gradually cleared and recovered good vision, revealing, however, yellowish and pigmented areas of the fundus.

17. Reported by Steitz⁴² in 1935.

An adult male injured his right eye with a broom handle. The vision of the injured eye was lost at once. Local treatment and dressings were applied. The left eye developed pain and blurring of vision two months after the injury. Examination of the right eye showed ciliary injection, a prominence nasally beneath the bulbar conjunctiva, a cloudy anterior chamber, absent iris at the nasal limbus, aphakia, hemorrhage on the anterior face of the vitreous, and vision equal to defective light projection. The left eye disclosed slight ciliary injection, hyperemia of the iris, a posterior synechia nasally, and visual acuity of 5/15. The right eye was enucleated. The inflammatory process in the left eye increased, with gradual failure of vision, total synechia, and cataract.

Microscopic study of the removed eye showed two subconjunctival scleral tears in the upper nasal quadrant with incarcerated iris and ciliary body. The lens, surrounded by connective tissue that was heavily infiltrated with lymphocytes and plasma cells, lay beneath the conjunctiva across the scleral wounds. Connective tissue, filled with plasma cells and epithelioid cells, occupied the space between the lips of the scleral tears. The iris and ciliary body were infiltrated, with occasional groups of epithelioid and giant cells in the uveal tract. The choroid was detached anteriorly by hemorrhage, and contained plasma cells up to the choriocapillaris. The retina was separated nasally and temporally.

18. Reported by the author⁴³ in 1943.

This patient was presented before the Ophthalmologic Section of the New York Academy of Medicine in a brief report. A detailed description of this interesting case is given below, together with a drawing and photomicrographs.

REPORT OF THE AUTHOR'S CASE

E. L. G., a white woman, aged 70 years, was seen on November 22, 1941, because of a "growth" of her left eye and failing vision of her right eye. She was referred to me by Dr. John Russell Twiss. The patient stated that the vision of her left eye had been poor since the age of 18 years, when this eye suffered from "keratitis and recurring intraocular hemorrhages." The onset of her present illness followed a fall eight weeks before I examined her. She said that she had struck her left temple region, and that a severe hemorrhage appeared in her left eye, followed by the presence of an elevated "growth" on the nasal side of the eyeball. Four weeks later, the vision of her right eye became obscured by "cobwebs," and

she consulted a local oculist who prescribed atropine drops and hot compresses, and advised removal of her seven remaining teeth. The extraction of the teeth had no effect upon her eyes, and the vision of her right eye failed rapidly.

Examination of her eyes, eight weeks after her fall, showed an inflamed soft right eye, with a plastic exudate in the anterior chamber, many posterior synechiae, incipient senile cataract, a cloudy vitreous, and vision equal to perception

case without evidence of cardiac failure (blood pressure 174/112), generalized arteriosclerosis, and chronic arthritis. Laboratory studies showed an elevated erythrocyte sedimentation rate (42 mm. at the end of one hour), clotting time of 4.5 minutes, bleeding time of 2 minutes, negative blood Wassermann test and Kline reactions, and normal urinalysis. The complete blood count revealed: RBC 4,360,000, hemoglobin 82 percent, WBC 6,800, color index 0.9. Differential white-

Fig. 1 (Perera). Photograph of artist's drawing of patient's left eye, showing prolapsed iris beneath bulbar conjunctiva and luxated lens above this.

of hand movements. The left eye disclosed marked congestion, a central corneal opacity, a projecting mass of inflamed prolapsed iris beneath the bulbar conjunctiva in the lower nasal quadrant, a yellowish rounded subconjunctival mass superior to the dislodged iris, normal intraocular pressure by palpation, and vision equal to the perception of light.

A thorough medical investigation by Dr. Twiss revealed a mild chronic disease of the tonsils, obesity (weight 182 pounds), hypertensive cardiovascular dis-

cell count: polymorphonuclears 74 percent, small lymphocytes 20 percent, large lymphocytes 1 percent, monocytes 4 percent, basophiles 1 percent. Blood chemistry investigations showed: Urea nitrogen 8.5 mg. percent, sugar 142.8 mg. percent, cholesterol 224 mg. percent, and icterus index 7.9 units.

The patient was admitted to the Institute of Ophthalmology of Presbyterian Hospital, New York City, with the clinical diagnosis of subconjunctival rupture of the left globe, subconjunctival dislo-

cation of the lens and iris of the left eye, and probable sympathetic ophthalmia. Dr. A. B. Reese kindly examined this patient and agreed with the diagnosis. Several kodachrome photographs of the patient's left eye were made. From these, Mr. E. G. Bethke made a colored drawing which was photographed by Mr. A. Marfaing and is shown in figure 1.

and blindness. The patient has recently suffered from a cerebral hemorrhage with accompanying aphasia and hemiplegia.

Pathologic study of microscopic sections of the removed left eyeball is recorded in the files of the Department of Pathology of the Institute of Ophthalmology of Presbyterian Hospital as follows:

Fig. 2 (Perera). Photomicrograph of patient's left eyeball in cross-section to show intercalary rupture of globe and lens lying beneath the bulbar conjunctiva. A portion of the granulomatous mass of extruded iris tissue overlies the lens. Note the edematous swelling of the anterior lip of the scleral rupture and the flat detachment of the retina posteriorly. The ciliary body on the side of the rupture is heavily infiltrated, and the entire choroid is thickened and infiltrated.

Enucleation of the patient's left eye was performed 9½ weeks after the accident. Healing of the socket was uneventful. The right eyeball has gone on to shrinkage and degeneration, with yellowish-green discoloration of the iris, complete posterior synechia, dense cataract,

"The outer coat of the eyeball shows a rupture in the intercalary region nasally with the presence of the entire lens in its capsule and a mass of infiltrated uveal tissue lying beneath the nasal bulbar conjunctiva (figs. 2 and 3). The uveal tissue contains dispersed and disorganized

masses of pigment and a massive granulomatous reaction forming a tumorlike lesion made up principally of epithelioid cells and lymphocytes, with some plasma cells and a few giant cells (fig. 4). This mass of tissue lies inferior to the site of the lens and overlaps it without, however, invading the lens capsule. There is a con-

marked edema, with thickening and separation of its lamellas by fluid. The central cornea reveals loss of Bowman's membrane and the presence of a moderate amount of scar tissue in the superficial stroma. The intercalary region temporarily, on the side opposite the rupture, shows a distinct rarefaction. The anterior

Fig. 3 (Perera). Photomicrograph of horizontal cross-section of globe to show tumorlike mass of granulomatous tissue containing disintegrating iris on the outer surface of the sclera. The retinal detachment and massive choroidal infiltration are seen inferiorly.

siderable amount of pigment phagocytosis. The lens shows wrinkling of its capsule and peripheral vacuolar changes in its cortex at the equator. The interior of the globe shows extensive changes, characterized by a massive thickening and infiltration of the choroid and ciliary body with epithelioid cells, lymphocytes and rare giant cells (fig. 5). The cornea adjacent to the site of the rupture shows

chamber contains albuminous pink-staining fluid, and the entire iris is absent from the interior of the globe. On the anterior surface of the vitreous lies a thin fibrous membrane which continues nasally to merge with a dense connective-tissue mass lying on the internal surface of the ciliary body nasally and extending into the area of the interruption of the continuity of the cornea and sclera. The internal sur-

face of the ciliary body, especially nasally, shows disintegration and disorganization of the epithelium, both pigmented and nonpigmented, and an outpouring of leukocytes between the ciliary processes. The retina shows irregular areas of flat detachment over its entire extent, with a deeply staining homogeneous material

the disc and a slight lymphocytic infiltration of its pial sheath. The vitreous reveals some areas of hemorrhage on the surface of the ciliary body nasally and beneath the membrane anteriorly.

Conclusions. This eye, which is the seat of old corneal scarring, has suffered a rupture at the nasal intercalary region

Fig. 4 (Perera). Higher power photomicrograph of an area in the granulomatous mass on the surface of the eyeball. In the center of the picture is a rounded area of giant cells and large epithelioid cells with disintegrated and phagocytosed pigment derived from the broken-down iris. Around this are masses of epithelioid cells infiltrated with lymphocytes and plasma cells.

separating the detached retina from the underlying degenerated pigment epithelium. Nasally the retina has been drawn forward over the pars plana of the ciliary body. with extrusion of the iris and the entire lens beneath the conjunctiva. The extruded uveal tissue has formed a tumorlike granulomatous mass of epithelioid cells, lymphocytes, and occasional giant cells. The interior of the globe shows a massive granulomatous infiltration of the uveal tract and a flat detachment of the retina.

Pathologic diagnosis: Injuries—indirect rupture of globe; injuries—subconjunctival luxation of lens; sympathetic ophthalmia following injury; cornea—scars. (The pathologic report was made by the author, and kindly reviewed and confirmed by Dr. A. B. Reese.)

brief. In cases 4 and 9, the pathologic report of the enucleated eye was suggestive of the diagnosis of sympathetic ophthalmia. In cases 5, 6, 8, and 10, the account of the removed globe was inadequate to make the pathologic confirmation of sympathetic ophthalmia. In Donaldson's patient,

Fig. 5 (Perera). Photomicrograph of cross-section of posterior layers of eyeball, showing flat detachment of retina, massive infiltration and thickening of choroid with epithelioid cells, lymphocytes, and plasma cells, and dispersal of choroidal pigment.

COMMENT AND STATISTICAL SURVEY

A careful critical analysis of the foregoing case reports leads to the conclusion that the diagnosis of sympathetic ophthalmia following subconjunctival rupture of the eyeball was proved by the pathologic examination of the injured globe in eight instances (cases 11, 12, 13, 14, 15, 16, 17, and 18). Of these, the clinical history of case 13 was not given, and the description of case 16 was very

case 10, the onset of sympathetic uveitis in the uninjured eye occurred 27 days after removal of the damaged eyeball. Enucleation was not performed in cases 1, 2, 3, and 7, but the histories of these patients are clinically characteristic of sympathetic ophthalmia. In cases 1 and 3 the authors stated that the iris was not seen when the inflammatory process had subsided in the injured eye; but in these eyes the lens was dislocated under the

bulbar conjunctiva in the first and probably into the vitreous in the second, and there was no other evidence that the iris was lost at the time of the injury.

The rarity of sympathetic ophthalmia following subconjunctival rupture of the eyeball makes its frequency difficult to evaluate. The Report of the Committee on Sympathetic Ophthalmitis of the Ophthalmological Society of the United Kingdom⁴⁴ in 1886 uncovered 211 examples of the disease. Of these, only three fall within the criteria which I have stated for sympathetic ophthalmia following rupture of the globe. Some authors, such as Alt,⁴⁵ Theobald,¹² Joy,⁷ Trowbridge,⁸ and Irvine,⁴ reported large series of patients with sympathetic ophthalmia with no instances of cases falling in the group described in this paper. Of the 15 proved examples of sympathetic ophthalmia from the collection of the Department of Pathology of the Institute of Ophthalmology of Presbyterian Hospital, New York City, my case was the only one which followed subconjunctival rupture of the eyeball. A review of 715 cases of sympathetic ophthalmia, taken from series of cases reported in the literature, revealed that only 12 are among those covered by the title of this paper. It thus appears that about 1.6 percent of cases of sympathetic ophthalmia result from subconjunctival rupture of the eyeball.

In a discussion of subconjunctival luxation of the lens, Ask⁴⁶ emphasized the great danger of sympathetic ophthalmia, and advised, contrary to the opinion of many earlier writers, the immediate removal of the dislocated lens and prolapsed uvea, or enucleation. The incidence of sympathetic ophthalmia after subconjunctival rupture of the globe with subconjunctival luxation of the lens varied from 20 to 40 percent, according to different investigators, but most of their examples do not fit into the more rigid

criteria which have been employed in this paper.

The sex distribution of the 18 cases reported in this thesis shows 8 males and 5 females, with the sex of 5 patients not given. Their ages varied from 12 to 70 years, and was not recorded in four instances.

TABLE 1

DATA FROM 18 CASES OF SYMPATHETIC OPHTHALMIA FOLLOWING SUBCONJUNCTIVAL RUPTURE

Case	Sex	Age	Time Interval before Onset in Uninjured Eye
1	male	—	7 weeks
2	male	38	6 weeks
3	male	50	5 weeks
4	male	58	6 weeks
5	female	40	4 weeks
6	—	48	7 weeks
7	male	45	25 days
8	male	12	3 weeks
9	female	43	10 months
10	female	33	47 days
11	male	33	6 weeks
12	female	56	6 weeks
13	—	—	—
14	—	41	44 days
15	—	61	4 months
16	—	—	5 weeks
17	male	—	2 months
18	female	70	4 weeks

The interval of time between the rupture of one eyeball and the onset of inflammation in the uninjured eye varied from 3 weeks to 10 months. The cause of the scleral rupture was injury by a cow's horn in 8 patients, contusion from other objects in 8 cases, and unknown in 2 instances.

DISCUSSION

In all patients with subconjunctival rupture of the sclera, it is difficult if not impossible to exclude the possibility of an unnoticed minute wound of the conjunctiva. Even serial microscopic sections of the enucleated eyeball might not reveal a tiny tear of the conjunctiva which had healed during the interval of time between the injury and the removal of the globe. Since it is known that an infective

agent or virus can pass through intact conjunctiva, the presence or absence of a tiny conjunctival wound bears no weight in casting light upon the etiology of sympathetic ophthalmia.

My study is in accord with the findings of most writers that there is incarceration of lens or uveal tissue in nearly all instances of sympathetic ophthalmia, whether resulting from perforating traumatic or operative wound or from subconjunctival rupture. This fact, together with the certainty that sympathetic ophthalmia does develop in some patients after subconjunctival rupture of the globe, tends to favor the theory that allergy to uveal tissue or pigment plays a part in the etiology of sympathetic ophthalmia.

As Meller⁴⁷ has pointed out, there may be need for changing our conceptions of sympathetic ophthalmia, which may be present in cases other than those with perforating injuries. One form of so-called idiopathic uveitis may be idiopathic sympathetic ophthalmia, developing in patients whose uveas, injured through causes other than perforating wounds, have become sensitive to the etiologic agent of this disease.

The histologic features of sympathetic ophthalmia, including the widespread pigment phagocytosis, are compatible with the allergy theory of its causation, as Friedenwald²¹ and Woods²² have emphasized. My microscopic studies of the 15 examples of sympathetic ophthalmia in the collection at the Institute of Ophthalmology are consistent with their work.

SUMMARY

A brief survey of sympathetic ophthalmia is given. This includes its incidence, the rarity of its occurrence following subconjunctival rupture of the eyeball, a short discussion of its etiology, and a presentation of its pathologic findings.

The need for a critical study of the cases reported in the literature as examples of sympathetic ophthalmia is presented.

Records of patients with sympathetic ophthalmia following subconjunctival rupture of the eyeball have been reviewed.

This paper deals only with uncomplicated examples of sympathetic ophthalmia resulting from a subconjunctival rupture of the globe, including the complete report of the author's case. It seemed logical to exclude instances of surgical intervention following the injury, as well as those cases in which the conjunctiva was visibly torn, or an intraocular structure was lost at the time of the injury.

Of the 18 cases culled from the literature, only 8 were proved by pathologic study to be examples of sympathetic ophthalmia following subconjunctival rupture of the eyeball. The remaining 10 cases were considered to be presumptively valid enough to be included.

The frequency, sex distribution, and age of patients with sympathetic ophthalmia following subconjunctival rupture of the globe are given, as well as the interval of time between the injury and the onset of inflammation in the uninjured eye.

It is impossible to eliminate the possibility of a minute conjunctival wound in these cases.

This investigation is in accord with the studies of most authors who report the incarceration of lens or uveal tissue in nearly all cases of sympathetic ophthalmia.

The findings of the author are consistent with the theory that allergy to uveal tissue plays a part in the etiology of sympathetic ophthalmia.

WERNICKE'S DISEASE* (ENCEPHALITIS HEMORRHAGICA SUPERIORIS)

DANIEL KRAVITZ, M.D.

Brooklyn, New York

AND

ROBERT H. STOCKFISCH, M.D.

Jersey City, New Jersey

In 1881, Wernicke¹ described a clinical syndrome characterized by clouding of consciousness, varying ophthalmoplegias, and ataxia. Patients who were more severely affected went into stupor or into states of excitement, and many died within a few days. The cases Wernicke reported were all in inebriates, and he felt that some toxin, possibly alcohol, was the cause of the disease.

Shortly after this Jacobäus² described cases of the syndrome in which there was peripheral-nerve and spinal-cord involvement and he felt that Wernicke's description of the disease was too circumscribed. Many years later, Bender and Schilder³ came to the same conclusion.

Although all the early cases reported were in alcoholics, Jacobäus advanced the idea, without offering proof, that alcohol *per se* was not the cause of the disease but that some nutritional disturbance was a contributing factor. This view was further advanced by Bender and Schilder.

In the last decade many reports of the disease in nonalcoholic patients began to appear in the literature. Of 14 cases reported by Neuberger,⁴ 10 had malignancy of the gastrointestinal tract and 4 had chronic gastritis.

Wagener and Weir⁵ reported three cases, two of the patients had severe post-operative vomiting and one the pernicious vomiting of pregnancy; all three developed ocular-muscle paralyses. Campbell and Beggert⁶ also reported the disease

in patients suffering from chronic gastrointestinal disturbances and persistent vomiting from other causes.

Jolliffe and his co-workers⁷ reported 27 cases of the syndrome that had been observed at Bellevue Hospital between the years 1935 to 1940; only 3 of these were in nonalcoholics. They concluded that some metabolic factors, rather than alcoholism *per se*, were the cause of the disease.

In 1938, Alexander and his co-workers⁸ made a most important contribution to the understanding of the causes of this disease.

They found that if all the vitamins except thiamine chloride were fed to pigeons, the pigeons regularly developed Wernicke's syndrome. On the other hand, if all vitamins, except thiamine chloride, were removed from the diet, Wernicke's syndrome did not develop.

Von Grosz⁹ reported muscle paralyses in cases of vitamin-B deficiency and they and Wagener¹⁰ noted the rapidity of cure if large doses of vitamin-B were promptly given.

Prickett, Salmon, and Schroeder¹¹ produced peripheral-nerve degeneration in rats by feeding them diets deficient in vitamin B. Axelrod, Spies, and Elvehjem¹² ruled out riboflavin as a cause of the disease when they showed that the riboflavin content in the blood and muscles was the same in pellagrous as in normal controls. They also showed that in vitamin-B deficiency there was a lack of a co-enzyme factor which in some way affected the oxidation process in muscles.

* Read before the Brooklyn Ophthalmological Society in February, 1945.

According to Veasey,¹³ thiamine chloride is the antineuritic or beriberi-preventing factor in the vitamin-B complex.

It is now agreed that thiamine chloride is a catalyst for carbohydrate metabolism. If absent, carbohydrate metabolism is arrested at the pyruvic-acid stage; and, in fact, the amount of pyruvic acid is a measure of the deficiency. Pyruvic acid is toxic to nerve tissue, and its deleterious action is enhanced by the presence of other noxious agents, notably alcohol, and by diabetes and other toxemias, such as the toxemia of pregnancy. The most severe cases, particularly those ending fatally, are in the chronic alcoholics; hence the disease originally was thought to be due to alcoholism. Alcoholism results in a chronic gastroenteritis which interferes with vitamin and food absorption and it also causes damage to the liver, an organ which plays a vital role in vitamin metabolism.

The pathologic changes in this disease have been extensively studied. According to Jolliffe, the lesions are confined to the periventricular gray matter, and are characterized by small foci of degeneration and varicose deformities of the blood vessels. There is subacute necrosis of the adjoining parenchyma, and small petechial hemorrhages are frequently found throughout the lesions. The areas most constantly involved are the nuclei of the thalami, hypothalami, and mammillary bodies. The region of the midbrain, especially the third and fourth nuclei, the nuclei of the vestibular nerves, and the dorsal nuclei of the vagi are also frequently involved.

Gamper¹⁴ pointed out the constancy of involvement of the mammillary bodies in the Korsakoff syndrome, a condition due to alcoholism.

Ecker and Waltman¹⁵ stated that the lesions in Wernicke's disease are most common in the gray structures of the

brain near the third and fourth nuclei and in the region of the aqueduct of Sylvius.

The treatment is thiamine chloride in large doses. Prickett, Salmon, and Schroeder showed that the disease could be cured only in its early stages. Later, damage to the nerves becomes irreversible, and even massive doses cannot cause regeneration of the nerve tissue. In fact, the condition may progress and even end fatally.

Wagener made the interesting observation that the oculomotor paralyses are the most resistant to treatment, a fact shown in case 1. Conversely, Jolliffe noted that in those cases in which the ocular motor nerves showed signs of clearing, recovery from the disease was usually complete and rapid. This is exemplified in the third case here reported.

Wernicke's disease is a neuro-ophthalmologic disorder due to thiamine-chloride deficiency. Alcoholism and other diseases that interfere with food and vitamin absorption from the gastrointestinal tract make the condition more severe and more difficult to cure. Wernicke's syndrome may be more frequent than the reports seem to indicate, and in some of the cases in which there are ocular-motor paralyses the latter may be a symptom of this disease, rather than the more commonly diagnosed "stroke" or "vascular sclerosis."

The recognition of this condition is important because early and adequate therapy is necessary to effect a cure.

CASE REPORTS

Case 1. D. Y., Chinese, male, single, aged 39 years, a laundry worker, seven years in this country, came to the clinic of the Jersey City Medical Center on November 17, 1939, with a history that about one year ago he noticed that his eyes were becoming prominent. He thought that the right eye was first in-

involved. During the past few months the prominence of the eyes had become progressively worse. He also noticed that he had to turn his head to see objects to either side of him.

Because of the prominence of the eyes, a thyrotoxicosis was diagnosed, but as several basal-metabolism readings, taken over a period of months, varied from plus 6 to plus 14, that diagnosis was dropped.

On June 17, 1940, the patient was referred to the Post Graduate Hospital for study.

Physical examination. The patient had a wide staring expression, such as is seen in advanced cases of thyrotoxicosis. The upper lids were markedly retracted. The exophthalmometer readings were 17 mm. right and 15 mm. left eye. There were a definite lid lag on movement of both eyes downward, and a complete absence of upward gaze. Both superior recti were completely paretic. The inferior obliques and the external recti were almost entirely paretic. The internal recti were moderately weak, but convergence was completely absent. The superior obliques were only mildly involved. The pupils were equal and regular and reacted to light and accommodation. The sensitivity of the cornea of the left eye was reduced, and there was marked congestion of the conjunctival veins. The fundi were normal. Except for numerous nodules on the skin, no other physical abnormalities were found.

The possible diagnoses were sarcoid, lymphoplasma, and trichinosis. The possibility of thyrotoxicosis was considered and ruled out.

Thorough laboratory studies were made. X-ray studies of the chest, long bones, and skull were negative for pathologic change. Examinations for trichinosis were negative. Except for a mild

anemia, the blood showed no abnormalities. The urine was negative for Bence-Jones proteins. Five stool specimens were positive for the ova of *Clonorchis sinensis*, and sections of several tumors removed from the skin showed them to be areas of mucinous degeneration of the subcutis.

The patient was discharged from the Hospital on June 28, 1940, and referred back to the outpatient department with no definite diagnosis.

Somewhat later, the possibility of Wer-nicke's disease suggested itself and the patient was placed on large doses of thiamine chloride and vitamin-B complex.

On January 3, 1940, the external recti showed increased motility and there was some improvement in the functions of the inferior obliques. By April, the exophthalmos was becoming less apparent, and there was further improvement in the functions of the ocular muscles. By January, 1941, all ocular movements, except upward gaze, were practically normal.

The patient was last seen on April 4, 1941. The staring expression due to the retraction of the lids had practically disappeared and, except for a slight weakness in upward gaze, the ocular-muscle paralyzes had disappeared.

Case 2. M. H., a man, aged 22 years, an accountant, came to the Jersey City Medical Center on July 6, 1941, with the complaint that three months ago his eyes began to feel tired after work and that he had headaches in the evening. He developed dizzy spells during which objects in the room seemed to move to the left. About two months ago, he noticed that the left eye was unable to look to the left and that the left side of his face and forehead was paralyzed. About two weeks ago, vomiting without preceding nausea started. The vomiting was somewhat forceful and came about two to three

times daily. Since he had begun vomiting, the dizzy spells had become more frequent. There was no history of any acute illness preceding the onset of the symptoms. The past history was irrelevant.

The patient was admitted to the neurologic service with the following findings:

There was slight swaying on the Romberg test. The deep reflexes on the right were slightly hyperactive. The palpebral fissure of the left eye was narrower than that of the right. The pupils were equal and regular and reacted to light and accommodation. The external rectus and the obliques of the left eye were completely paralyzed. The left internal rectus was weak; the right internal rectus and the obliques were completely paralyzed, while the external rectus was very weak. The other ocular muscles were not affected. The fundi were normal. There was a complete peripheral facial paralysis on the left side. The neurologic and medical examinations were otherwise negative.

Triple-typhoid vaccine, starting with 25 million and doubling the dose each time was given on July 10, 11, 12, and 13, 1941, with fair febrile reactions.

The patient continued to grow worse and left the hospital on July 17, 1941, without a diagnosis. About six weeks later a high-vitamin diet together with large amounts of vitamin B₁ was given by mouth.

On November 1, 1941, the ocular motor functions had improved about 90 percent, and the left facial paralysis had disappeared. A month later the patient was completely cured of all paralyses and has remained so since.

Case 3. R. R., a woman married, aged 33 years, came to the outpatient department of the Brooklyn Hospital on September 18, 1944, with a history of menorrhagia and spotting for a long time.

Examination showed vaginal bleeding, and she was admitted to the Hospital on the gynecologic service.

September 19th, under spinal anesthesia, a dilatation and curettage and a cauterization of a cervical ulcer were performed. While making rounds a few days later, it was noticed that the patient had ptosis of both upper lids and other ocular-muscle weaknesses. This, the patient said, had been present for several weeks prior to her admission to the Hospital. She was transferred on September 26, 1944, to the medical service with a diagnosis of myasthenia gravis.

Examination showed ptosis of both upper lids, very poor ability to converge, and weakness of all ocular muscles. There was cheilosis at the angles of the mouth, and the tongue was very red, smooth, and appeared to be enlarged. A diagnosis of vitamin-B deficiency was made.

Further history elicited the fact that the patient had been on a substandard diet for a long time.

Large doses of vitamin-B complex and a high-vitamin diet were prescribed.

On October 6, 1944, all the ocular-muscle paralyses and weaknesses had disappeared. There was still some cheilosis present at the angles of the mouth and the tongue was still moderately red and smooth. The patient was discharged from the Hospital as cured on October 7, 1944. By November 1, 1944, the cheilosis and glossitis had completely disappeared.

SUMMARY

Three cases of superior encephalitis of the Wernicke type are reported, wherein there was no history of alcoholism, but which were due to dietary deficiency.

There were complete cures in the second and third cases and an almost complete cure in case 1. In the last-named, the disease had been present for a much

longer time and the symptoms were much more severe and had reached the irreversible stage, but fortunately to only a small extent. It is interesting to note that only in case 3 were other features of vitamin-B deficiency present; namely, cheilosis and glossitis.

ANGIOID STREAKS IN THE DEEP LAYERS OF THE RETINA*

ARTHUR J. BEDELL, M.D.
Albany, New York

Angioid streaks, those peculiar bands forming a more or less complete peripapillary ring with radiating branches, have been discussed for years. A host of concomitant signs have been written into the clinical descriptions, and emphasis has often been placed on them as though they were a distinctive part of the disease.

Numerous theories have been advanced to explain them. Some of the discarded ones have been slightly changed and re-introduced, but since the advent of the rupture of Bruch's membrane theory many writers have accepted it as a proved fact. I am not as yet convinced that it is more than a hypothesis, for, obviously, it does not explain all cases. Some papers have been published that lead the uninformed to believe that the rupture and the accompanying pseudoxanthoma elasticum are part of the same process. This certainly is not true in all instances.

An extensive review of the literature is not included for two reasons: first, because some cases have been reported more than once by different recorders, causing considerable duplication, and, second, the work has been very well done by Scholz. He not only compiled the bibliography but also published several fundus photographs illustrating small streaks, very broad ones, macular degeneration, and choroidal hemorrhage. His review does not register the work of Dimmer and Pillat, who published the first book of fundus photographs which includes several angioid streaks, nor does it mention those shown by me in 1932 and subsequently published. He has, however, done an excellent job, for anyone who has at-

tempted a complete bibliography has found to his annoyance that some reports were overlooked.

After going over the Scholz review, the reader is referred to Wagener's enlightening, discursive paper.

Law presents an excellent article which commands attention because of his superior professional skill. What he describes as pigmentary debris and extracellular uveal pigment is sufficient, I believe, to explain the appearance of most of the streaks, and especially the great peripheral collections of round, red spots. I am, however, at a loss to understand why folds produce such a strange lack of even a semblance to a regular outline—that is, a moth-eaten edge. I agree with one of his conclusions, that "there is no necessity to invoke the occurrence of clefts in Bruch's membrane in explanation of angioid streaks, since none is present in this case."

Batten includes many of the accompanying diseases and suggests linking angioid streaks with them. This may prove to be true, but at this time, after going over many fundus photographs of vascular disease and a few of angioid streaks, I wonder if the theory has not outrun the facts.

It is futile to continue academic discussions when photographs furnish convincing proof. The streaks are flat. Vail made this point in 1928. The photographs I took of the eyes in the case which he presented at the meeting of the American Medical Association's Section of Ophthalmology seemed to substantiate his claim, as have all that I have studied since that time. I am unable to confirm the observations made by Clay, that pressure on the globe causes the streaks to disappear, nor have

* Presented at the eightieth annual meeting of the American Ophthalmological Society, at Hot Springs, Virginia, June, 1944.

I succeeded in establishing any familial tendency or relation to injury.

Without photographs, it is very difficult to be certain that a given streak has become larger or longer, or even to determine when it disappears, for an overshadowing retinal disease, such as common senile macular degeneration or retinal hemorrhage, may, for a time, completely obscure it. Later, when the blood or exudate has disappeared, the unchanged streak is found in its old location. There are, however, verified cases in which the streaks have widened, lengthened, and reached to the granular, spotted, peripheral fundus. In other cases, the faint, grayish-yellow limiting borders have become wider and wider until eventually only a delicate tracing of the red streak remained. The observer must be very careful to analyze each streak to avoid error in labeling an impression a fact.

Scholz reports that only 46 patients were seen for over a year. He referred to Oeller's patient, whom Fleischer, in 1938, reported as having had good vision for 23 years after the streaks were discovered. Later, macular involvement reduced it. This is supporting evidence of my contention that the presence of other signs is by no means proof of common cause. Cases have been reported wherein the streaks became thinner, darker, and less distinct. Zentmayer's case is illustrative.

Scholz states: "Of patients who were followed for more than a year, 33 percent showed an increase in the number of streaks; in 56 percent the condition remained unchanged; and in 10 percent the streaks decreased in number. The vision remained, on the whole, unchanged except as influenced by macular pathologic changes."

This is interesting, but I wonder what the conclusions might have been had they been based on the documentary evidence

of photographs. I am inclined to believe that they would be different.

In some patients, as we will show, Segrist pigment spots develop on the streaks. The bands following choroidal or retinal detachment do not look like angioid streaks.

There is complete agreement among competent authors that the streaks are always beneath the retinal vessels, but there is some difference of opinion in relation to their position when choroiditis develops. I believe they are in front of the scars, and that they can be traced over the pigment or atrophy.

Narrow circumpapillary atrophy as such has nothing to do with the streaks, for it is a common finding in eyes without any pathologic condition, a fact readily conceded after the examination of a series of selected stereoscopic fundus photographs.

Furthermore, when degenerative macular lesions develop, they follow the usual clinical course of deep retinal or superficial choroidal hemorrhage, exudate, edema, expanding ring of blood, and increasing exudate. After many months the recurring hemorrhages stop, the exudate becomes organized, and the scar persists through life. I do not conceive this to be an integral part of angioid streaks.

The object of this paper is to record the observations made during the past several years on angioid streaks, with special details of the findings in four cases, one of which was under observation for a short time, the second for 4 years, the third for 8 years, and the fourth for 14 years.

CASE REPORTS

CASE 1. M. S., a man, aged 36 years, healthy, single, in the Armed Forces, came for an examination because he was dissatisfied with his Army glasses.

Examination. Right eye: vision 20/100. With a $-2.50\text{D. sph.} \approx -50\text{D. cyl. ax. } 180^\circ$ it was 20/20. The pupil was 3 mm. in diameter, regular, and active. The media were clear and the disc was slightly oval. The retinal vessels followed a common pattern and were normal. The inferior artery and vein paralleled each other for some distance until the artery crossed the vein without indentation or any variation in caliber. The superior temporal artery crossed in front of the vein and was without pathologic change. Surrounding the temporal and superior half of the disc was a pale, indefinitely outlined, narrow arc, the base of which was slightly uneven, thickest at the superior edge of the nerve-head. The outer border of this depigmented zone was the darker. There was a fine, red line beneath the retinal vessels starting from about the 5-o'clock position, and extending inferiorly to the 9-o'clock. This streak was not of equal diameter throughout, and it was not exactly in the same level—deepest at 9 o'clock and most forward at 5 o'clock. Near the nasal side of the disc there were a few interlacing angioid streaks. The background of the fundus was mottled with moderately heavy pigment. The dark, macular area was clearly and distinctly outlined; the center had a slightly granular appearance, and the vessels supplying it were of normal size and distribution.

Left eye: vision 20/200. With a $-2.75\text{D. sph.} \approx -50\text{D. cyl. ax. } 180^\circ$ it was 20/15. The disc was clearly and sharply outlined, with an increased prominence of the translucent nasal half. The border was clearly discernible, with a narrow temporal pigmented margin. The retinal vessels and the macular region were normal. The latter was outlined by fine, stippled pigmentation. The fundus background was mottled. The angioid streaks were arranged in an extremely

delicate network, separated from the disc by a pale arc. They were, with the exception of a short isolated one, near the inferior temporal disc border, all confined to the nasal side, thin, red lines, more or less concentric to the disc. There were two dark spots almost as red as the streaks, one at the 3-o'clock and the other at 4-o'clock position. The peripheral fundus was negative in each eye.

Diagnosis. This was a case of very fine streaks unassociated with any other fundus change, thereby proving that it is possible to have angioid streaks in otherwise negative fundi.

CASE 2. M. O'C., a woman, aged 30 years, married, has been under observation for four years. The only interesting point in her history was the fact that "10 years ago there was considerable question as to whether I should continue at school because my sight was defective." Two and one-half years prior to examination she lost her vision for one month. At that time, her tonsils and all her upper teeth were removed, although there was no evidence of dental disease. Her Wassermann reactions were negative.

Examination. When she first came under supervision the vision of the right eye was 20/30 and Type 1. Her total refractive error was $+ .50$. The pupil was 3 mm. in diameter, regular, and active. The media were clear. The disc, sharply and distinctly outlined, bulged forward about 2 diopters. The swelling was translucent and, of course, the nasal side projected farther. Surrounding the disc was an interrupted pigment line with very slight general pigmentation in the inferior segment and a broad, irregular, oval, depigmented zone from the 8- to the 11-o'clock position. This, in its broadest dimension, was wider than the disc and faded imperceptibly into the normal sur-

rounding structures. The retinal vessels were of normal size and distribution.

Beneath them and surrounding the disc was a mesh of red streaks, varying in width from the widest at the 9-o'clock position to the narrowest at about the

Fig. 1 (Bedell). Case 2. Right eye. July 27, 1940. Branched angioid streaks beneath the retinal tree; two large patches of choroidal pigmentation.

12:30-o'clock position. They all radiated from just beyond the margin of the nerve-head but did not come from exactly the same circumferential area. They were most numerous to the upper, inner side, where they formed an irregular network. Several streaks extended a considerable distance. One, passing anterior to a small choroidal scar, was more than 3 disc diameters in length, and more than twice the width of the largest vein, the end partly obscured by a gray covering and surrounding cloudiness. The other two were shorter and narrower.

There were four streaks in the inferior nasal quadrant. Some of them were the same width as the upper ones. A streak, extending almost vertically downward from the 6-o'clock position, was considerably broader but shorter, the surface was uneven and the color varied; in places

it was quite red, in other spots practically as pale as the contiguous fundus. The longest streak started at about the 5-o'clock position, and passed almost straight downward; the outline was wavy, the edge serrated, the caliber variable, and after extending 4 disc diameters it merged into the red, granular periphery.

The streaks on the temporal side were divided into three groups; the superior temporal ones consisted of two major branches which arose from near the disc border, were beneath the corresponding retinal vessels, and in front of a small choroidal scar.

An interesting streak extended from the 9-o'clock position for about $3\frac{1}{2}$ disc diameters. It was faint, on the whitish base of depigmented peripapillary atrophy. About 1 disc diameter from the disc there was a round dark patch of choroidal pigment with pale borders, over which the streak could be traced. Farther temporally, there was a short space where the red, granular streak was again clearly seen before it passed over a linear, choroidal scar above the irregularly pigmented macula to become a narrow, bright-red tortuous line before it entered the red speckled peripheral region.

Beneath the inferior temporal artery was a long, somewhat spearhead-shaped mass of dark, almost black, choroidal pigment. The retinal artery passed in front of it. Between the two largest choroidal scars, in the inferior temporal region, proximate to the disc, there was an irregular, granular, oblique red streak. On the nasal side, at about the 4-o'clock position a long streak extended obliquely toward the periphery and was traceable for 4 disc diameters. Part of its course paralleled the vein (fig. 1).

Vision of the left eye was 20/20, total refractive error +.50D. sph. \approx +.25D. cyl. ax. 75°. The pupil was 3 mm.

in diameter, regular, and active. The media were clear. The retinal vessels were normal. The surface of the oval, elevated disc was uneven, with several colloid masses on the nasal side. These were translucent, and the pigment on the disc

for 3 disc diameters. It narrowed abruptly, and finally merged into the red granular dots which encroached upon the otherwise clear macular area.

Three years later. In the right eye there was a wider zone of choroidal absorption

Fig. 2 (Bedell). Case 2. Left eye. July 27, 1940. Angioid streaks to the nasal side of the prominent disc.

Fig. 3 (Bedell). Case 2. Left eye. September 22, 1943. A very large, flat streak curves about the inferior border of the macular area.

could be dimly seen through them. Smaller collections were near the inferior disc border. The disc was clearly outlined by a faint arc of pigmentation. Beyond it was a paler band with a dark and finely granular edge. Surrounding the disc was a network of fine reddish streaks. These were smaller than those observed in the right eye, but otherwise they had the same characteristic tortuous outline, variable pigmentation, and, in places—particularly at the 8:30-o'clock position—there was a faint line about a portion of the streak. Altogether, there were 10 radiations from the circumpapillary ring. Some streaks were several disc diameters in length and were often parallel to and directly beneath the retinal vessels (fig. 2).

On the temporal side the circumpapillary ring was less defined, and there was only one broad oblique streak, which stretched from the 3:30-o'clock position

about the disc, the red streak near the macula was brighter. In the periphery of the fundus there were more fine red granules and the superior streaks were wider.

In the left eye, the changes had been slight; two were noteworthy: (1) At the end of the oblique streak which curved about the lower margin of the macular area the granules were more widely separated and (2) the faint, oblique, pale band near its termination had increased slightly in width, with irregular pigmentation in and about it (fig. 3). There has been no perceptible change in the past year.

CASE 3. A woman, aged 29 years, has been photographed at irregular intervals for the past eight years, and was referred by Dr. T. L. Terry of Boston, with the report that he had found no evidence of

osteitis deformans, but that she had a small patch of pseudoxanthoma elasticum on her neck.

Examination. On May 6, 1937, the patient seemed to be entirely well; she had never had any serious illness. The ex-

but not at an equal distance from its border, was a broad dark streak of brownish-red granules. From the upper edge where the band was closest to the nervehead, three streaks fanned outward. The broadest was short and divided into

Fig. 4 (Bedell). Case 3. Right eye. May 6, 1937. Broad, circumpapillary streaks, and a white-walled superior temporal one. A wide, white band above the macula.

Fig. 5 (Bedell). Case 3. Left eye. May 6, 1937. Heavily pigmented streaks on the nasal side, and a very delicate, vertical one between the disc and macula.

amination of her fundi, confirmed by the photographs, proves that new streaks do develop and that others undergo distinctive changes, such as an increase in the whitish streak margin, the formation of small, white, nodular masses, an occasional deposit of black pigment in or over the streak, and also fine white flecks near the distal end of the streaks where they merge into the region of red granules. The broad streaks in the right eye showed marked differences in color, in places a pale gray and in others dark red. In the left eye, there was a progressive broadening and lengthening of the streak and the oblique white band became whiter.

Vision of the right eye was 20/50; with a $-0.75D.$ sph. it was 20/20. The disc was almost round, with a small, central excavation. The retinal vessels were normal. Completely surrounding the disc,

two parts about one-fifth disc diameter above the border. The longest and narrowest was at the 10:30-o'clock position, whereas at the 9-o'clock there was a long streak which passed above the macula and was partially concealed by an overlying long, linear, white scar (fig. 4). There were several small, pigmentary collections about the macula. From the inferior border a broad streak, consisting of what appeared to be dark red granules, had an irregular outline, and extended downward about 3 disc diameters. Fine white dots were near its frayed end. On the nasal side there were no radiations from the peripapillary band. All of the streaks were deeper than the retinal vessels.

Vision of the left eye was 20/30; with a $-0.75D.$ sph. it was 20/15. The pupil was 3.5 mm. in diameter, regular and active. The media were clear. The retinal

veins and arteries were of normal size and distribution. The clearly and distinctly outlined disc was surrounded by an irregularly pigmented ring similar to that in the right eye, but the branching angioid streaks were narrow and less pigmented.

Three years later, this particular streak was a jagged band the width of the largest vein. It tapered to a thin line several disc diameters from the inferior temporal border of the disc. Examination showed that from this streak, at about the 3-o'clock

Fig. 6 (Bedell). Case 3. Right eye. February 5, 1944. Seven years later. The streaks are decidedly broader. The white lines along the streak have increased; the band in the macular region is smaller.

Fig. 7 (Bedell). Case 3. Left eye. February 5, 1944. Increased pigmentation in all streaks, especially marked in the one between disc and macula.

From the circumpapillary ring, there was an upward extension, twice the width of the vein, which tapered into a pigmented area similar to that described in the right eye. The outline of all of the streaks was ragged. There were two other streaks, one at the 10-o'clock and the other near the 6-o'clock position. On the temporal side of the disc there were three distinct dark-red spots, about three quarters of a disc diameter from the temporal border. A faint, white line, with a central, thin, reddish streak, extended from near the temporal border at the 2:30-o'clock position and passed above the macular region. There was a scarcely perceptible, fine streak with an extremely delicate prolongation, starting about one-half disc diameter from the temporal border of the disc, slightly above the white line and passing downward toward the 5-o'clock position (fig. 5).

position, a branch was in the center of the pale white streak which was much less defined than formerly and, instead of being a continuous line, was broken by two whitish spots. The pale zone surrounding the disc had increased in width at the lower border, where a ragged streak and a small artery passed over it.

The streaks in the upper half of the fundus showed marked wall changes. Whitish spots developed over several of them and a few black spots, ophthalmoscopically similar to Segriss's dots, were present in one.

Later in the same year the oblique streak above the macula was less visible, but two distal whitish spots were found. The fine, granular, dark-red spots had spread from the temporal side until they were only about one disc diameter from the fovea.

By June 3, 1943 a white spot had de-

veloped alongside the enlarging, inferior temporal streak.

When last examined, February 5, 1944, the individual spots along the course of the temporal streaks were brighter, but through each the angioid streak could be traced. The gross pattern had, with the exception of the temporal streak, remained much as it was in the beginning (figs. 6 and 7).

Summary. The changes in the left eye, which developed in eight years of observation, were the development of new streaks, of white spots along the course of several, a decrease in the visibility of the walls of one, an increased opacity near the inferior border of the disc and the encroachment of the red, granular, peripheral spots.

In the right eye, white spots formed along some of the streaks. The broad, white, irregularly outlined, superior macular streak became narrower and dark, granular spots collected on its surface.

When last examined, the vision of the right eye was 20/20; of the left eye 20/20. There was an irregularly enlarged, horizontally oval, blind spot in the right eye.

With the red light, the streaks were dark; with the yellow, chocolate brown; with the green, darker than with the yellow; whereas when illuminated with the unfiltered electric bulb they were dark, except where the light was reflected at an acute angle, when they were almost as red as the adjacent retinal vessels. The redness was most marked in the largest streak and best seen by focusing the light band on the retinal border of the streak.

The fourth case was recorded in the address of the Chairman of the Section of Ophthalmology, American Medical Association, in 1935. It has remained buried, for no writer on angioid streaks has ever mentioned it. I then stated that the streaks

were either in the deep choroid or between the choroid and the sclera. Now, as a result of more experience, better instruments, and improved photographic film, I believe them to be more superficial.

This is a very important résumé for the patient has been under observation from his forty-second to his present sixty-fourth year. During this time he developed varicose veins in his legs, a left-sided hemiopia, and his blood pressure ranged from 70/50 to the present 178/110. He has not developed any skin changes. His kidney-function tests and Wassermann were negative.

CASE 4. A vigorous-appearing printer was first examined on December 22, 1930. The Vision of the right eye was 20/15; total refractive error +.50D. cyl. ax. 90°. The pupil was 3 mm. in diameter, regular, and active. The media were clear. The clearly outlined normal-colored disc was surrounded by an irregular, partially depigmented zone, widest one-half disc diameter at the superior and inferior portions. The nasal inferior part of the disc was elevated, and the vessels curved over it. The retinal vessels were of normal size and distribution. Surrounding the disc, and forming the outer border of the pale circumpapillary area, was a brownish-red granular angioid streak from which many branches radiated. They were most numerous and shortest on the nasal side, where they formed a meshwork of broad bands. They were longest to the temporal side, where one streak paralleled the course of the temporal artery. The border of this and other streaks was pale. The macular area was clear (fig. 8).

Externally, the left eye was similar to the right. Vision was 20/20. The small disc was flat and clearly outlined by broad, angioid streaks, double on the nasal side, single on the temporal. From this red, granular ring, several broad bands were

projected, curiously frayed below, more defined above and nasally, and more granular on the temporal side. Frequently the streak seemed to lie on a pale band that was wider than the red portion.

The remaining part of the fundus was

near the red and speckled macula (fig. 9).

By 1938, the macular area was pallid, with a slight speckling. The streak on the nasal side, extending from the 9-o'clock position, was about 2 disc diameters in length, with a very small,

Fig. 8 (Bedell). Case 4. Right eye. December 22, 1930. Many flat streaks about the disc. Clear macula.

Fig. 9 (Bedell). Case 4. Right eye. May 6, 1937. Increased pigmentation and widening of the streaks especially above the macula.

somewhat mottled; dark specks were within two disc diameters of the broad band that surrounded the nervehead. There was a definite ampulliform dilatation to the inferior nasal side of the disc. The streak extensions from this were granular; in places the pigment seemed to be absent, and the reduction in width of the streak was striking. Scattered about the disc were several granular spots of the same appearance but in no way connected with the streaks themselves. The macula was uninvolved, and the field of vision normal.

On May 7, 1937, the clearly outlined disc of the right eye was partially surrounded by a pallid zone, the outer margin of which was a reddish, granular streak with the extensions previously described. The darkest bands were in the inferior nasal quadrant, short, curved, thick. The temporal one was a yellowish-white stripe

superficial, linear hemorrhage about the size of the largest retinal vein. The disc was pale and the surface rounded.

No great alterations were observed in the right eye until 1943, when the vision was reduced to 20/50. There was an irregularly outlined edema of the macula, with a pink base and several dark spots roughly arranged in two circles, the inner about one-fifth disc diameter in size and the outer about four fifths.

There was a partial dissolution of the overlying retina, with a yellowish-gray edge and many very minute yellow spots. Between the macula and the disc were two fresh hemorrhages: one, a narrow line, fairly sharp and distinct; the other was one-fourth disc diameter in width. Both were beneath the retinal vessels. There was another extravasation on the superior temporal border of the pale disc

about one-half by one-fifth disc diameter in size on the same retinal level. The disc had not changed in color but near the lower border was a white triangle, the distal margin of which was a streak. The retinal arteries were reduced in caliber.

three times the width of the largest vein. Its edge was frayed and it merged into the red, dotted periphery. The superior vertical streak became narrow before it reached the speckled area. The inferior streak, the most uneven in width, could

Fig. 10 (Bedell). Case 4. Left eye. January 3, 1939. Broad streaks about the disc. Irregular pigmentation above the macula.

The angioid streaks—a little wider, darker than the surrounding retina, and much darker than the fresh retinal blood—were still present, but because of the color of the entire fundus they were not so well differentiated.

In 1937, the streaks in the left eye showed practically no changes. The superior portion of the macular area was, however, definitely more mottled with several pale spots.

By 1939, this region showed a more diffuse pallor in a zone about five-sixths of the disc diameter. The retinal vessels were uninterrupted, but the background was distinctly redder than the adjacent retina; the streak forming its upper border was narrow. The disc surface was uneven. There were several pale spots with the characteristic reflex of drusen. The superior streak had a fuzzy outline. The upper nasal streak was in some places

Fig. 11 (Bedell). Case 4. Right eye. April 19, 1943. Extensive retinal hemorrhages on the disc and between it and the macula with beginning macular degeneration. The streaks remain.

be traced to the red dots (fig. 10).

In 1943, the vision of the left eye was reduced to 20/200, unimproved with glasses. The disc was pale yellowish, but the border remained sharply outlined and the zone surrounding it was practically unchanged. The streaks were a dark reddish brown. There were a few isolated yellow accumulations about the streaks and a recent black spot at about the 2-o'clock position on the disc border. The streaks near 7 o'clock were distinct and more attenuated (figs. 11, 12, 13).

The angioid streaks were less sharply contrasted because of the macular edema, small superficial hemorrhages, and many fine white exudates dispersed about the lower half, most numerous and thickest near the disc. The macular region was similar in color but smaller than that in the right eye. The definition of streak

detail was as clear. The superior macular area streak was unchanged in size or length.

The differences between retinal hemorrhage and angiod streak were clearly seen.

in fundi that were otherwise negative.

During the progress of the disease, whitish or small black spots may appear in the streak.

The disc may be elevated and translucent.

Fig. 12 (Bedell). Case 4. Left eye. April 19, 1943. Very large, broad, serrated streaks about the nasal side of the disc with irregular pigmentation to the temporal side.

Fig. 13 (Bedell). Case 4. Left eye. April 7, 1944. Broad streaks. White specks partially surround the degenerated macula. Several fine hemorrhages.

CONCLUSIONS

Angiod streaks radiate from a circle surrounding the optic disc. The extensions from this ring vary in width or length; the individual pattern is distinctive.

Streaks may be very small, thin lines of a reddish color, or several times wider than the largest retinal vein and of a dark chocolate color. They may interlace and form a meshwork which is usually near the disc, or they may branch. They may fade into the adjacent tissues, have a frayed end which is sometimes overshoot by a gray clouding, or extend into the reddish granular periphery. The center of the streak may be so thin and pale that it is almost invisible, or the streak may be completely covered by a yellowish-white band. There may be an increase or a decrease in the granules which reflect the color. Angiod streaks have been found

When the disease has been existent for a long and unpredictable time, other fundus changes may become engrafted, notably massive pigment collections (usually dark brown or black), isolated small or extensive retinal and choroidal hemorrhages, or hemorrhages in and about the macula with the characteristic tendency to become absorbed when fresh ones appear, forming a circle or oval in which the retina first becomes edematous, then infiltrated, and, finally, permanently scarred.

It is probable that in all cases of advanced angiod streaks the equatorial zone and perhaps the extreme peripheral fundus are covered by fine, granular-appearing red dots. These spots have received very little attention in the literature and yet a careful scrutiny of the published drawings will show that some artists have seen them.

Several fundus photographs have been published. The earliest ones were in the Dimmer and Pillat atlas.

Too much notice has been given to the late or coincident signs and too little to the more accurate description of the life history of the streaks. Even in cases wherein the retina is the site of large hemorrhages it has been proved that the streaks are unchanged by the overlying blood.

A few observers have reported swelling of the nervehead. Law and others have recorded it, and it was present in two of the cases here cited.

No new theory is presented as to the cause of angioid streaks, nor is any theory so far advanced accepted without reservations.

SUMMARY

Very few cases of angioid streaks have been observed for long periods, and, as far as I know, none of them has been repeatedly photographed.

The white or yellow lines which follow

choroidal or retinal detachment have neither the color nor the texture of angioid streaks.

The streaks seem flat, but are not of uniform thickness, and the white spots which develop along some of them do not seem to be choroidal exudates.

Competent pathologists have examined many eyes with ruptures of Bruch's membrane, but have not found angioid streaks.

The theory that the streaks are blood vessels can, in the light of our present knowledge, be discounted, for no vessels have been found where the streaks develop and it does not seem probable that blood vessels could have the serrated edge so frequently seen in angioid streaks.

Streaks are presented here in which no hemorrhage was present and there was no evidence that there ever had been any.

Finally, even in the presence of very large retinal hemorrhages the streaks remain isolated and in no way connected with the fresh blood.

DISCUSSION

DR. GRADY CLAY, Atlanta, Ga.: In 1932, I first published in this country the association of angioid streaks and pseudoxanthoma elasticum, and since that time the reported association has become too frequent to be coincidental and therefore

the pathologic changes must be related. Since that original report I have seen 63 more cases; 30 percent of these cases are associated with pseudoxanthoma elasticum and 15 percent are familial. I have found no other related disease in this

group. Nineteen patients in my series were hospitalized and a very careful study of this group revealed no other associated diseases. One with only a few streaks died recently from a hypertensive disease. An autopsy was obtained, also one eye. The complete report is not yet ready for publication.

I still believe the disease is a disease of the blood vessels associated with elastic-tissue degeneration, and that the earliest changes seen are hemorrhages and the formation of the streaks in the choroid. After this acute period has passed, which may be a year or two, hemorrhages are rarely seen and no more streaks develop, and from this time on there is a slowly developing choroidal atrophy in the areas of the streaks, and in these areas the streaks will entirely disappear. Why should there develop such a definite area of choroidal atrophy if this disease is not primarily a disease in the choroid and a blood-vessel disease?

In my opinion, the true pathologic picture is not yet known, and unless one is fortunate to secure an eye early in the course of the disease it will not be known, for secondary changes too greatly alter the pathologic picture.

Pseudoxanthoma elasticum occurs without angioid streaks, and vice versa. All cases that I have seen which show few streaks do not show pseudoxanthoma elasticum. The degree of skin involvement is in direct relationship to the degree of fundal pathology. A patient showing the most marked disease of the two conditions is a woman aged 52 years, and the skin condition was noted by her mother at 3 years of age. She has a niece, 15 years old, showing the two conditions in an exaggerated type—the youngest I have seen.

The disease is most frequently seen in the routine examination of the fundus for as it does not affect vision unless a

streak should extend to the macula. In such cases hemorrhages are likely to occur and the end-result may resemble a disciform senile degeneration. I believe that many such macular lesions may be associated with angioid streaks.

DR. WILLIAM ZENTMAYER, Philadelphia, Pa.: From what has been said and shown here today, there seem to be as many opinions among the clinicians as among the pathologists as to what constitutes "angioid streaks." I should like to give a brief abstract of the clinical history of a typical case of angioid streaks of the retina observed over a period of 36 years. The case was reported before this Society in 1909, and was repeatedly shown over several years before the College of Physicians of Philadelphia. These are the fundi as painted at that time.

The patient, a man, aged 33 years, came to the Eye Clinic at St. Mary's Hospital in November, 1908, complaining of pain and dimness of vision in the right eye. This was due to a dendriform ulcer of the cornea. In the routine examination the angioid streaks in the retina were revealed. To summarize the findings: In the fundus of each eye there was a system of ramifying and anastomosing pigmented streaks which extended outward into the fundus from a similar band which surrounded crescents of grayish-yellow retinochoroidal disturbance about the disc. The streaks were beneath the retinal vessels and tapered toward the periphery of the fundus, which was the site of marked retinochoroidal changes. The color of the streaks was, in general, black, but in places there were islands of bright-red color. In O.D. there was a horizontally oval hemorrhage below the fovea.

In 1927, the patient was again shown at the College of Physicians and the following description of the media and fundi was given:

"O.D. Two vacuoles in upper part of lens, one large and one small. The disc yellowish gray and the nasal border veiled. The choroidal vessels in central area show varying degrees of sclerosis. There are several dense black pigment masses about 1 d.d. in size at the macula. The broken yellowed pigmented zone about the disc noted earlier has almost completely disappeared. There are still sections of fairly characteristic angioid streaks, following the course of the superior temporal vessels, near the equator below and one far out along the course of the superior nasal vessels. The latter is continued as a whitish streak running toward the disc. There is a black pigment mass lying beneath the superior nasal artery about 3 d.d. from the disc. Marked sclerosis of choroidal vessels was present. No active changes were noted.

"O.S. Media clear. Disc is about the same color as in the right eye. The veins are engorged. The sclerosis of choroidal circulation is more pronounced in the central area than in O.D. The pigment masses at the macula are also denser and larger than in the right eye. Of the pigment bands earlier seen, there remain only a section of one running horizontally a distance of about 3 d.d. near the equator, and one extending from upper margin of disc along the course of the superior temporal vessels. There is a greenish crescent about the nasal side edge of the disc bordered with a pigment band as originally seen.

"In both eyes, the periphery of fundus shows the pale yellowish dots and pigment originally noted.

"In both eyes the tension was normal.

"Vision: Right eye, 5/30. Left eye, 0.5/60."

In 1934, at the request of Dr. T. L. Terry, I had studies again made of the patient's physical condition to determine whether there was any evidence of Paget's disease. The roentgenograms were nega-

tive for evidence of Paget's disease, but there was some calcification in the region of the sella turica, probably within the internal carotid artery. At that time I again examined the patient's eyes. The description of the fundi showed that the changes noted in 1927 had progressed. There was no longer any evidence of the former angioid streaks and in the right eye there was an area beneath the superior temporal vessel suggestive of circinate retinitis.

The patient was seen again on May 18, 1944. O.D. There were a few vacuoles in the lens. The disc was somewhat waxy in appearance, but the gray zone which was formerly present about the disc has disappeared. Over most of the fundus there was a marked sclerosis of the choroidal vessels, with deep pigmentation of the intervacular spaces. In the macular region there were masses of dense pigment of irregular shape. In some portion of the fundus there was complete atrophy of the choroid.

O.S., media were clear. General appearance of the fundus about the same as in the right eye, only the areas of complete destruction of the choroid were most extensive and there was a denser massing of the pigment in the macular region. There were two extensive areas of almost complete atrophy, one along the course of the inferior nasal vessels and the second along the course of the inferior temporal vessels. Beneath the superior artery there was a vertical irregular area 3 d.d. in diameter, of whitish hue with a circinate appearance.

Vision: Right eye, 1/60. Left eye, 1/60.

About three months ago, the patient suffered a slight stroke affecting his speech and at the present has a systolic blood pressure of 210.

DR. F. P. CALHOUN, Atlanta, Ga.: In 1927, the late Thomas B. Holloway presented a paper before this Society on the subject of angioid streaks, and with his

characteristic thoroughness, reviewed the 56 cases then reported in the literature.

He noted that in four cases there was a familial tendency, and he commented that "if such an investigation had been made it is possible that the active coincidence would have been high."

At the same meeting I likewise presented "An unusual case of angioid streaks," and I pointed out that the family history of the patient strongly suggested a familial, vascular disease or degeneration, since one brother had died at an early age from a heart attack, a sister died of intestinal hemorrhage, and a living sister was reported having a bilateral central choroiditis, which, indeed, might have been an atrophy from a hemorrhage and not from an infection.

In 1938, Law reported a similar family history in connection with angioid streaks, one member dying of intestinal hemorrhage.

I now wish to present the very unusual and extensive pedigree of a family in which angioid streaks, skin lesions (which clinically resemble pseudoxanthoma elasticum), and distal hemorrhages were the dominant symptoms.

I am in agreement with Dr. Bedell that the fundus picture which is described as angioid streaks and its complications involving the macular region may be due to a variety of causes, one of which is a familial vascular degeneration. I know of no better way to explain it than to accept Hagedoorn's thesis.

DR. F. H. VERHOEFF, Boston, Mass.: I understand that Dr. Bedell concluded from his study that the condition known in the literature as angioid streaks is not an entity, but that the streaks may have various origins. Lindner pointed out that pigmented streaks can form over sclerotic choroidal vessels, and I demonstrated the nature of the pigmented streaks that sometimes result from separation of the

choroid. No doubt streaks may result from still other causes. Such streaks, however, do not produce the characteristic picture of the condition known as angioid streaks.

In 1928, when I reported the finding microscopically and macroscopically of many conspicuous streaks in the fundus of an enucleated eye, I felt sure that I had discovered the nature of angioid streaks, although none was present in the other eye. Up to that time, no microscopic examination of an eye with the typical ophthalmoscopic picture had been made, and my findings seemed to explain not only the streaks, but also the macular changes and the choroidal hemorrhages that sometimes occur.

The case, however, reported by Böck in 1938 has almost if not quite persuaded me that mine was not one of angioid streaks. Böck examined microscopically, *post mortem*, two eyes which had ophthalmoscopically shown typical angioid streaks. He not only failed to find choroidal ridges such as I had seen in my case, but did find in Bruch's membrane changes which seemed adequately to explain the streaks.

In 1939, Hagedoorn reported similar microscopic findings, but since the ophthalmoscopic examination was unsatisfactory his case is significant only when considered in connection with Böck's. Law, in 1938, concluded, after microscopic examination of an eye with angioid streaks, that the latter were due to retinal wrinkles. I feel sure that the findings he described were due to post-mortem changes.

Further examination of this eye should be made in the light of Böck's case. In Benedict's case, the eye, possibly on account of the way it was sectioned, showed neither choroidal ridges nor anything else that explained the streaks that had been seen ophthalmoscopically. The changes in Bruch's membrane found by Böck and

Hagedoorn were similar to, but generally more marked than, those I had often seen many years ago in senile eyes, and had described in collaboration with Dr. Sisson in 1926. The youngest patient in whose eyes we found them was aged 48 years. This fact is highly confusing because it suggests that angioid streaks should develop chiefly if not solely in senile eyes, whereas it is believed that they begin in early life even when they are first seen much later, for they have actually been observed in childhood. Other confusing facts are that, while many of the patients have pseudoxanthoma elasticum of the skin, a considerable number have well-marked Paget's disease of the bones, and that although a few have neither of these conditions, no case has been described in which the patient had both.

DR. RALPH I. LLOYD, Brooklyn, N. Y.: Rayner Batten has some very beautiful black-and-white and colored drawings of cases in a family seen over a period of years, but they do not compare with Dr. Bedell's stereoscopic kodachromes. One of the French authors has observed several members of a family over quite a period, but the illustrations are sketches and not well done. I will take your time just long enough to show the fundi of three sisters to emphasize the fact that there are many cases of macular degeneration seen, but, if there are no angioid stripes, we are at a loss for a definitive designation. One of these sisters has typical bilateral macular degeneration with angioid stripes; a second sister has all of this in one eye and the macular degeneration but no stripes in the other eye, and the third sister has only slight macular changes.

DR. BEDELL, closing: Dr. Clay who has seen many angioid streaks said that in 63 recent cases 30 percent were associated

with pseudoxanthoma elasticum. It is difficult for me to consider that the skin disease and the angioid streaks are anything more than coincidental changes.

He further reports that he has seen no streaks develop after the acute period has passed. You will recall that I showed how a streak developed and how it has continued to increase in both length and width.

I agree with Dr. Clay's observation that macular hemorrhages occur and that the end result of them is similar to disciform degeneration, but my interpretation is different. I consider the hemorrhages to be coincident with the angioid streaks and not part of the same disease, for I have seen hundreds of macular degenerations without streaks.

Dr. Zentmayer records the results of his careful observations of a patient for over 36 years. This is unique and worthy of critical examination, for the fundus changes were not only angioid streaks and choroidal-vessel sclerosis, but also hypertensive retinal disease.

Dr. Calhoun has made notable contributions to our knowledge of angioid streaks, especially in the field of familial vascular diseases, and if, eventually, the cause of the streaks is found to be a vascular degeneration, his contributions will rank high in the list of early investigations.

Dr. Verhoeff referred to his pathologic examinations, and it is satisfying to note that the changes in Bruch's membrane, ascribed by some as the cause of angioid streaks, were similar to and not more marked than he had often seen in senile eyes.

The drawings shown by Dr. Lloyd illustrated some of the confusing fundus changes.

It was gratifying to note the interest taken in the paper, and I thank those who have discussed it.

DIABETIC IRIDOPATHY*

C. A. CLAPP, M.D.

Baltimore, Maryland

Changes in the iris associated with diabetic conditions have been reported for many years. Some of these conditions are inflammatory whereas others are apparently not associated with inflammation. This latter group, I think, should be called iridopathy. Since they are apparently more frequent than the former and may even be confused with malignancy, I believe that a discussion of the changes and points in differential diagnosis may be helpful.

The noninflammatory changes in the iris were described by Parsons,¹ who stated that an extreme edema of the pigment layer of the iris with the formation of cystlike spaces occurred, as well as the freeing of pigment. Kamocki,² in 1887, found similar changes as illustrated in figure 1. It is evident that not only was the pigment epithelium of the iris edematous, with cystlike formations, but also there was an area of proliferation of the cells in the anterior capsule of the lens. Ball³ also illustrated (fig. 2) the condition of edema and cystic formations in the pigment-epithelial layer and called attention to the occurrence of free pigment in the aqueous in cases of cataract extraction so that the aqueous appeared even black in color. Roemer and Foster⁴ referred to the pigment layer as being swollen and the pigment often scattered over large spaces.

Zentmayer,⁵ in 1913, reported a case of cataract extraction in a diabetic wherein

a cast of the posterior pigmented surface came away. Duke-Elder⁶ mentions softening of the posterior layer of the iris and an infiltration of the tissues with glycogen and rarely a lipemia. The infiltration of glycogen into the nerve fibers of the iris was demonstrated by Hoffman,⁷ in 1914. Moore⁸ found only one case of iritis in 62 cases of diabetes, but he states that marked changes in the epithelium of the posterior surface of the iris are almost constantly present and that thickening of the stroma may occur.

In 1935, Waite and Beetham⁹ reported their findings in 2,002 diabetic patients and by comparison in 457 nondiabetic ones. They found evidences of depigmentation of the iris in 6 percent of the diabetics and in only 2 percent of the nondiabetics, with pigment deposits on the posterior surface of the cornea in 11.5 percent of the diabetics and in 5 percent of the nondiabetics, with about the same proportion of cases of pigment deposits on the anterior surface of the lens, 2.8 percent: 1.8 percent. The authors suggest that this disturbance of the pigment in the iris may be due to the storage of glycogen in the tissues.

Leopold,¹⁰ in a recent article on ocular findings in diabetes which had been controlled for a period of 10 years, states that treatment had no effect on motility of ocular pigment and that iritis was not influenced by treatment. No case of rubeosis diabetica iridis was seen in the 100 cases reported. He also stated that depigmentation occurred in the older-age group of patients. In his last treatise on the eye, Tassman¹¹ states that the most frequent change is edema and swelling of the pigment epithelium with liberation of

*From the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital and the Johns Hopkins University School of Medicine. Presented at the eightieth annual meeting of the American Ophthalmological Society, at Hot Springs, Virginia, June, 1944.

Fig. 2 (Clapp). Proliferated pigment epithelial layer with edema (Ball³).

free pigment. The stroma may become atrophic.

Villani,¹² in 1934, was able to demonstrate in experimental diabetes in animals, edema, thickening, and some vacuoles in the epithelial layer of the iris and ciliary body, but the changes seem more marked in the iris.

Practically all of the pathologic mate-

is again seen the thickening of the pigmented epithelial layer with numerous vacuoles present. This patient also had an acute attack of glaucoma with tension of 85 mm. Hg.

In the case represented by figure 5 is seen a marked thickening of the pigmented area with vacuoles, especially at the pupillary margin, but also some ec-

Fig. 3 (Clapp). Photomicrograph of the iris showing thickening of epithelial layer with large vacuoles in a white woman, aged 34 years, who had severe diabetes, with secondary glaucoma.

rial in my hands available for study showed marked changes in the pigment-epithelial layer, but many of the eyes were removed because of a painful glaucoma so that it is difficult to evaluate as to whether the changes were all due to the diabetes or partially due to the secondary complications.
